A Cost-Effectiveness Analysis of Exercise as a Health Promotion Activity

EVRIDIKI I. HATZIANDREU, MD, MPH, JEFFREY P. KOPLAN, MD, MPH, MILTON C. WEINSTEIN, PHD, CARL J. CASPERSEN, PHD, AND KENNETH E. WARNER, PHD

Abstract: We used cost-effectiveness analysis to estimate the health and economic implications of exercise in preventing coronary heart disease (CHD). We assumed that nonexercisers have a relative risk of 2.0 for a CHD event. Two hypothetical cohorts (one with exercise and the other without exercise) of 1,000 35-year-old men were followed for 30 years to observe differences in the number of CHD events, life expectancy, and quality-adjusted life expectancy. We used jogging as an example to calculate cost, injury rates, adherence, and the value of time spent. Both direct and indirect costs associated with exercise, injury, and treating CHD were considered. We estimate that exercising regularly results in 78.1 fewer CHD events and 1,138.3 Quality Adjusted Life Years (QALYs) gained over the 30-year study period. Under our base case assumptions, which include indirect costs such as time spent in exercise, exercise does not produce economic savings. However, the cost per QALY gained of $11,313 is favorable when compared with other preventive or therapeutic interventions for CHD. The value of time spent is a crucial factor, influencing whether exercise is a cost-saving activity. In an alternative model, where all members of the cohort exercise for one year, and then only those who like it or are neutral continue, exercise produces net economic savings as well as reducing morbidity. (*Am J Public Health* 1988; 78:1417–1421.)

Introduction

Regular aerobic exercise is increasingly being viewed by health professionals as a key behavioral ingredient in reducing the risk of illness, particularly illness associated with heart disease. The "fitness craze" has emerged as an integral component of the broader concern with health promotion, with exercise explicitly recognized in the US Public Health Service's health promotion and disease prevention objectives for the nation.[1] In recent years the presumed cardiovascular benefits of exercise have received convincing empirical support.[2–4] Accordingly and increasingly, the medical profession has come to recognize and prescribe exercise as a preventive and rehabilitative therapy.

Many health promotion advocates emphasize also the economic benefits of exercise, in addition to its contribution to better health.[5] Because both the economic and medical dimensions of exercise are subjects of substantial interest, we examine the cost-effectiveness of exercise as a primary prevention medical technology. Our interests are in the health and economic implications of exercise as compared with its absence and in using exercise as an alternative to common medical interventions designed to address potential or existing heart disease. In addition, we examine the issue of whether exercise consumes more or less time than it saves in increased life expectancy.

Methods

We used decision analysis and cost-effectiveness analysis to compare a regular exercise regimen with its absence in cohorts of 1,000 35-year-old men, followed for 30 years. We defined exercise as leisure time physical activity that consumes 2,000 kcal per week. Jogging was used as an example to calculate costs, injury rates, adherence, and the value of the time spent. Exercise was considered to be a prescriptive medical intervention, analogous to chronic antihypertensive or hypoglycemic treatment. Cost-effective is a relative and subjective concept defined as "having an additional benefit worth the additional cost."[6] Beneficial programs that yield net cost savings are automatically cost-effective, but net cost saving is not necessary for a program to be judged cost-effective.

Using epidemiologic data, we estimated the number of fatal and nonfatal coronary heart disease (CHD) events that would be expected to occur over time in each cohort. We considered the consequences of CHD events to be their direct medical care cost and their effects on life expectancy and reduced quality of life. Thus, our measures of the health effectiveness of exercise were reductions in the numbers of CHD events, gains in life expectancy, and gains in quality-adjusted life expectancy. These effectiveness measures served as denominators in our cost-effectiveness ratios. The numerators of the ratio represent various measures of the difference between the incurred costs of the two strategies. We considered both direct costs and savings associated with an exercise regimen (direct costs, including equipment and clothing, as well as the medical cost of injuries, and savings consisting of the avoidance of treatment for CHD events) and indirect costs and benefits, respectively (time spent in the exercise program and healthy time gained as a result of CHD events prevented). Our outcome measures are cost (direct or direct plus indirect) per year of life saved, cost per quality-adjusted life year (QALY) saved, and cost per CHD death averted. All future costs and years of life saved were discounted at a real annual rate of 3 per cent to determine their present value. We chose to discount health benefits (future years of life saved and cases averted) to maintain a common perspective on the value of both future costs and future health effects. Costs were measured at 1985 price and wage levels.

Definitions and Rates

Health events for which rates were required in the analysis were exercise-related injuries, CHD events, and non-CHD mortality. Injury was defined as an adverse health effect severe enough for the injured person to seek medical consultation. We estimated the annual probability of such injury to be 5 per cent, with 17 per cent of those injured

This paper, submitted to the Journal December 23, 1987, was revised and accepted for publication June 9, 1988.

Editor's Note: See also related editorial p 1413 this issue.

quitting jogging permanently because of the injury.[7] We assumed that the rate of injuries and quitting remained constant throughout the 30-year study period.

CHD events were considered to be death (sudden or nonsudden), myocardial infarction, or other CHD (angina pectoris and coronary insufficiency). Age-specific incidence rates for men were derived from the Framingham Heart Study.[8,9] These rates, however, represent combined population rates, which include those who do and those who do not exercise. We calculated separate rates for exercisers and nonexercisers by assuming that 10 per cent of all men exercise as defined previously and that exercise reduces the risk of CHD by 50 per cent.[10] Age-specific death rates for men for 1980 from all other causes except CHD were used.

In both the exercise and nonexercise cohorts, we separated those who experienced nonfatal CHD into subgroups and tracked them to determine the number of additional deaths occurring during the follow-up period. Annual mortality rates in these subgroups of persons with CHD histories were based on data from the American Heart Association (age-specific CHD deaths and prevalence of CHD). Persons injured due to exercise and unable to continue jogging were considered "quitters" (dropouts). We assumed that they did not engage in other forms of aerobic activity and that they experienced the CHD rates of non-exercisers from the year of quitting.

Costs

Exercise—The direct cost of exercise, the cost of equipment (running shoes, clothes, etc.), is estimated at $100 annually. Considering exercise to be a prescriptive medical intervention, we have included the cost of counseling a patient to undertake an exercise regimen as a direct cost. We assumed that this counseling would occur during a routine periodic examination and would represent 10 per cent of a 45-minute visit. We estimated the average cost of the history and examination portion of a routine physician visit to be $75.

To determine the indirect cost, we assumed five hours per week, including exercise time (nine minutes per mile, 20 miles per week) and preparation time (24 minutes, five times a week). In deriving the monetary value of this time, we used the results of a telephone survey of six exercise experts who estimated the proportions of participants in an exercise program who like it (55 per cent), dislike it (35 per cent), or are neutral (10 per cent). We assumed that those who are neutral toward exercise would value their time at $4.50 per hour (half the 1985 hourly wage.[11]) Those who dislike exercise would value their time at $9 per hour, the average hourly wage, whereas those who like exercise would view it as costless, the "enjoyment value" exactly canceling out the opportunity cost of time expended. Multiplying these monetary values by the survey proportions produced an average value of $3.57 per hour of exercise for the cohort.

Injury—For the direct medical cost of injury, we assumed that an average office visit costs $40, and 50 per cent of the injured have an x-ray taken, at an average cost of $50. For the indirect cost, we estimated the average hours of work lost because of injury.[7] Work time lost is less than one hour per injured person per year, which then multiplied by the average hourly wage, yields an estimate of $8 per injured person per year.

Coronary Heart Disease—We used published direct and indirect lifetime cost estimates for CHD.[9] Direct costs are emergency assistance, hospitalization, follow-up care, including office visits, tests, and medications, and possible coronary angiography and coronary artery bypass grafting. Indirect costs are losses of earnings due to disability and premature death. All costs were adjusted from 1980 to 1985 dollars.

Measures of Effectiveness

To measure the health effects of exercise programs, we calculated the expected number of CHD events and the gain in years of life saved to allow comparison with other preventive or therapeutic measures.[12] The gains in years of life expectancy were adjusted for changes in the quality of life due to decreased morbidity from nonfatal CHD. We calculated QALYs by assuming that each year which follows the onset of a nonfatal form of CHD is equal to .8 of a healthy year.[12] We calculated QALYs for exercise-related injuries by assuming that the quality of the time spent while injured was .9 of an equivalent uninjured time period.

Sensitivity Analysis

We performed sensitivity analyses to test several of our assumptions. First, we varied the relative risk for a CHD event from 1.5 to 2.5. In addition, we varied the prevalence of those who exercise from 10 per cent to 20 per cent; the discount rate from 0 per cent to 5 per cent; the direct cost of exercise from $100 to $200; the indirect cost of exercise from $2 to $13.50; and the QALY weight from .7 to .9.

Alternative Model

We have also considered an alternative (voluntary) approach, which ultimately would target the exercise program at those who consider it to be enjoyable, or are at least neutral. We assumed that persons who start exercising do so for a one-year trial. After that, those who like it or are neutral continue, whereas those who do not like it quit permanently. We used probabilities of liking or disliking exercise derived from the expert survey and applied the same cost assumptions.

Analysis of Time Trade-Off

Recent critiques of analysis of the life expectancy benefits of exercise have commented that exercisers consume as much time in exercise as they gain in life expectancy.[13] To examine this issue and to provide another perspective, we determined the balance between time spent on exercise and injuries and that gained from CHD prevention. In effect, this approach constitutes a time cost-benefit analysis of exercise. We used the same assumptions as in the base case cost-effectiveness analysis.

Results

Health Benefits of Exercise

Under the base case assumptions there were 78.1 fewer CHD events in the exercise cohort than in the nonexercisers (Table 1). Furthermore, because of gains in life expectancy and quality of life, there were 1,138.3 QALYs saved in the same cohort (529.8 if discounted) (Table 2).

Costs

The expected costs under the two alternatives are displayed in Table 3. Accounting for the indicated direct and indirect costs of exercise, injury, and disease, exercise does not produce economic savings. It costs $740,000 more in direct costs and $6 million more in total (direct and indirect) costs for the cohort of exercisers.

TABLE 1—Expected Events Occurring between Ages 35–64 in Cohorts of 1,000 Exercisers and Non-Exercisers

Exercise	No Exercise
Total CHD 197	118.9
Myocardial infarcts 85.6	51.5
Other CHD 81.9	49.3
Deaths (initial) 29.5	18.1
Additional Deaths* 26.7	14.2
Total CHD Deaths 56.2	32.3

*Deaths from CHD in cohort members whose initial event is MI or other CHD.

Cost-Effectiveness Ratics

Estimates of the cost-effectiveness of exercise in preventing CHD are presented for four different effectiveness measures: QALYs gained, years of life gained, CHD cases averted, and CHD deaths averted (Table 4). The costs per QALY gained when direct and total costs are considered are $1,395 and $11,313, respectively.

Sensitivity Analysis

Using discount rates of 0 per cent and 5 per cent produces total costs/QALY of $8,376 and $12,623, respectively (Figure 1). Using a relative risk for CHD for nonexercisers of 2.5 produces a cost/QALY of $6,596, whereas a relative risk of 1.5 produces a cost/QALY of $18,685. A prevalence rate of exercise of 20 per cent in the general population results in little change in the cost/QALY, $9,654. When QALY weights of .7 and .9 are used, the costs/QALY are $12,090 and $10,352, respectively. Doubling the direct costs of exercise to $200 increases the cost/QALY to $14,342. When the indirect cost of exercise is varied from the base case estimate of $3.57 per hour, the cost/QALY varies from no cost at $2 per hour ("break-even" point) to more than $24,061 per QALY when an average hourly wage of $9 is used (Figure 2).

Voluntary Approach to Exercise

With this alternative, voluntary approach, a gain of 345.4 QALY is expected for those who continue exercising (i.e., those who like it and those who are neutral). The results are presented in Tables 5 and 6. The health benefits are less than the QALYs gained in the main analysis (350.1 vs 529.8 QALYs); however, this voluntary approach to exercise yields net economic savings even when indirect costs are included ($23.13 million for exercisers vs $25.79 million for nonexercisers). People who do not like exercise quit and thus do not incur the cost of $9 per hour.

We determined the incremental cost and benefit of coercing those who simply do not like exercise to engage in jogging. The marginal cost-effectiveness ratio for the coerced population is $48,775 per QALY.

Analysis of Time Trade-off

When time is discounted, like any other cost or benefit, the cohort of the 1,000 men aged 35 who exercise regularly for the next 30 years spends a total of 522.7 years in exercising, whereas 530 years are gained by preventing CHD. The "benefit-cost" difference is positive by 7.3 years, representing a net gain of 2.7 days per member of the cohort. Without discounting, there are 730 years spent and 1,030 years gained, a "benefit-cost" difference of 300 years, or almost 110 days per cohort member.

TABLE 2—Years of Life Lost in 1,000 Exercisers and 1,000 Nonexercisers, Ages 35–64

	Not Discounted		Discounted*	
	Exercise (N=1000)	No Exercise (N=1000)	Exercise (N=1000)	No Exercise (N=1000)
Due to CHD				
from Death	672.2	1190.5	276.9	492.1
from morbidity (QALY)	899.9	1539.9	449.8	778.2
Due to Jogging Injury	20.0	—	13.8	—
Total	1592.1	2730.4	740.5	1270.3

Discussion

Previous studies have concluded that other disease prevention technologies are cost-effective relative to therapeutic health care expenditures,[14] and sometimes even produce net economic savings, e.g., fluoridation[15] and certain immunizations.[16,17] Recently, however, concern has been expressed that, in some instances, preventive measures for chronic illnesses may be less cost-effective than those for acute conditions, and further that preventive measures are not invariably more cost-effective than curative therapy.[18]

On the basis of our estimates and assumptions, exercise *is* a cost-effective approach to lowering the risk of CHD. Exercise costs $11,313 per QALY saved, including the cost of time spent, and $1,395 in direct costs, excluding indirect costs and benefits. These figures compare favorably with other published cost-effectiveness studies of CHD interventions.[12] Coronary artery bypass graft surgery with left main disease costs $5,000 per QALY when two-vessel disease is present. With mild angina the cost per QALY becomes $40,000. Treating hypertension varies from $25,000 per QALY (diastolic pressure of 95–104 mm Hg), to $65,000 per QALY (diastolic pressure 90–94 mm Hg). It should be

TABLE 4—Cost-Effectiveness Ratios*

Cost/CHD Case Averted	9,462	76,760
Cost/CHD Death Averted	30,920	250,836

*All costs and effectiveness measures discounted at 3 per cent per annum.

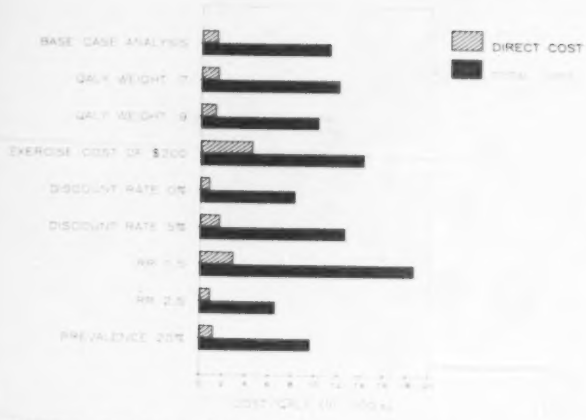

FIGURE 1—Sensitivity Analysis

emphasized, however, that these studies include direct costs only. It is conceivable that if these other CHD interventions saved a sufficient amount of productivity, then the inclusion of indirect benefits and costs would make these interventions more cost-effective.

The other cost-effectiveness studies of CHD interventions use only direct costs and savings, as is customary in cost-effectiveness analysis. We consider the indirect costs of time spent in exercise to be integral to this health intervention. An alternative approach to expressing cost-effectiveness could apply both direct and indirect costs but only direct benefits (our base case uses both direct and indirect benefits). This method results in a cost of $30,575 per QALY saved, or $75,232 per year of life saved. For the voluntary approach, exercise, which was cost saving when both direct and indirect costs and benefits were used, no longer saves money but is cost-effective at $9,180 per QALY saved, when total costs and only direct benefits are used. Thus even using this conservative approach, exercise remains comparable in cost-effectiveness to other CHD interventions. Significantly, evaluations of the costs of treatment of morbid conditions typically do not quantify the nonpecuniary costs of the disease and its treatment (i.e., the costs of pain and suffering).

The indirect cost of exercise is the most important

variable in influencing the results of this analysis. If the indirect cost (time spent in exercise) were valued as "no cost", then exercise would be cost-saving. However, we treat exercise time as having opportunity cost. Although the wage rate is commonly used in economic studies as the value of leisure time, we used one-half the wage rate as our basic measure of this opportunity cost. Both theory and empirical analysis suggest that the opportunity cost of the marginal leisure hour is less than the wage rate. We have used the estimate of half the wage rate produced by one of the few studies to examine this issue empirically.[19] Note that our treatment of the indirect cost of time for those who enjoy exercise is undoubtedly conservative for many people who are (or would be) willing to pay to exercise (as demonstrated by memberships in health clubs, for example). To these people, the benefits of exercise—immediate and perceived for the future—give exercise a net positive economic value.

Our results support an approach in which physicians would strongly urge patients to begin an exercise program on a trial basis for one year, with the expectation that only those persons who find it pleasurable or those who are neutral would be encouraged to continue. Such an approach was found to yield net cost savings, whereas an all-or-nothing approach in which "exercise-haters" are forced (in the model) to comply was cost-ineffective for this group ($48,775/QALY) compared with other methods of coronary heart disease prevention ($5,000 to $30,000 per QALY).

Our study focused on only cardiovascular health benefits of exercise. Other demonstrated health benefits of exercise include weight control, stress reduction, smoking cessation, and assistance in diabetes and hypertension management.[20] Quantification and inclusion of these benefits would improve the relative cost-effectiveness of exercise, possibly considerably.

Other forms of exercise also provide aerobic cardiovascular benefits. If used in a similar analysis, walking, swimming, and bicycling would require changing several variables. For example, walking might be a more enjoyable pastime for certain participants, thus lowering the indirect costs of exercise, but walking would require more time to achieve the same cardiovascular benefit, thereby increasing

TABLE 6—Costs under the Noncoercive Exercise Program ($ Million)*

*Present values at 3 per cent per annum.

the indirect costs. It would likely also reduce the direct costs of injury caused by the exercise.

Our study focused exclusively on 35-year-old men followed for 30 years. Further studies in exercise cost-effectiveness could consider women, various racial, ethnic or socioeconomic groups, other forms of exercise, and other health benefits. Adherence to an exercise regimen would affect the results of this analysis just as would adherence to a drug therapy. Partial adherence would reduce the cost (indirect) of exercise and the injury rate but also the cardiovascular benefits conferred by exercise. Thus, additional aspects that could be studied would be to vary adherence and the number of years of participation in an exercise program.

In another analysis of the health benefits of exercise, Paffenbarger *et al*,[21] estimated that exercise adds 2.15 years to the life expectancy. If we change some of the assumptions in our analysis (no discounting, full adherence, and no QALY adjustment), the total years gained for the cohort are 1,500, which is 1.5 years per person. The difference can be attributed to the fact that Paffenbarger, *et al*, looked at mortality from all causes from a very specific cohort (Harvard alumni), whereas we looked at increases in life expectancy by preventing CHD only, using national estimates.

To perform this analysis we have had to make several assumptions and use the best available data. The analysis can be improved in the future as more knowledge is gained on exercise and CHD, and then applied in a systematic and analytic framework.

For persons who enjoy the immediate pleasure and benefits of exercise, this activity is probably also a cost-effective measure in reducing risks of CHD. For others who find exercise a less pleasant activity, its cost-effectiveness is comparable to that of some drug therapies and surgical interventions.[12] Most persons logically would prefer to prevent a morbid condition rather than develop it and have it treated. However, they may require more immediate satisfaction to undertake and maintain a regular exercise regimen than the knowledge that it will reduce their long-term risk of CHD or that it is "cost-effective."

Divergence of the Recent Trends in Coronary Mortality for the Four Major Race-Sex Groups in the United States

CHRISTOPHER SEMPOS, PHD, RICHARD COOPER, MD, MARY GRACE KOVAR, DRPH, AND MARILYN MCMILLEN, PHD

Abstract: Since 1976 there has been a leveling off or slowdown in the rate of decline in coronary heart disease (CHD) mortality. The age-adjusted absolute annual rate of decline in CHD mortality rates during 1968–75 (Δ rate/100,000 population/year) was virtually identical for White males (−7.54), Black males (−7.85), and Black females (−7.20), and somewhat lower for White females (−4.25). During 1976–85, however, the secular trends diverged considerably. Age-adjusted rates continued to decline at the same annual rate for White males, while the decline was approximately half as steep for the other thre race-sex groups. During 1976–85 there was also a leveling off in the average annual per cent change in age-adjusted CHD mortality for Black males and females and White females when compared to 1968–75, while there was no change for White males. As a result, more than 40,000 White and Black females and Black males died of CHD in 1985 than would have died if CHD rates would have continued to decline at the 1968–75 trends. All comparisons were based on a reclassification of cause-of-death codes to maximize comparability between the 8th and 9th Revisions of the International Classification of Disease. These results suggest that the factors which have led to the continued decline in coronary heart disease may not have influenced all the demographic groups in this country equally over the last decade. (*Am J Public Health* 1988; 78:1422–1427.)

Introduction

Rapidly changing patterns of mortality from coronary heart disease (CHD) have been recognized in a wide range of countries over the last three decades.[1–3] Beginning in the mid-1960s, a tendency has been observed for countries with the highest rates to experience a rapid and consistent decline in mortality, most notably in the United States, Canada, Australia, New Zealand, and Finland, while Eastern Europe and the Soviet Union, which entered this period with lower rates, have seen a marked upturn in death rates from CHD.[3–6]

Although preventive campaigns and changes in the prevalence of risk factors for CHD may have contributed to the decline in the US, it has not been possible to provide precise estimates of all the factors affecting the downward trend in CHD mortality rates.[7–9] The prevalence and changes in the prevalence of the coronary risk factors have not been the same among the four major race-sex groups of the US[8,10–12]; it is therefore important to examine the secular trends in CHD mortality by sex and race to determine whether the changes are the same for the four groups.

Around 1980 it appeared that the decline in mortality for adults from all causes combined had slowed in the US, with a brief increase recorded for Blacks.[13] Since CHD is by far the most important single disease category determining adult mortality rates in the US, and it has been the primary component of significant secular trends in all-causes mortality, we examined trends in CHD mortality for the four major race-sex groups in the US with the hope of gaining insight into the two important questions: Has the decline in CHD mortality continued at the same rate in the 1980s? Has it continued at the same rate for each of the four largest race-sex groups?

Methods

Data Sources and Definitions

Age-adjusted and age-specific CHD mortality data for the four major race-sex groups were obtained from vital statistics data tabulated by the National Center for Health Statistics for the years 1968–85. Age-adjusted rates were computed by the direct method using the total US population of 1940 as the standard. During 1968–78 deaths were coded using the 8th revision of the International Classification of Diseases Adapted for Use in the United States (ICDA 8) and during 1979–85 they were coded using the 9th Revision of the ICD (ICD 9). We adjusted for the lack of comparability in coding rules between the two revisions by including in CHD for 1979–85 those ICD 9 categories that, for the most part, would have been coded in CHD categories in ICDA 8.[14] As a result, CHD during 1968–78 was defined using the category numbers for Ischemic Heart Disease (ICDA Nos. 410–413) and during 1979–1985 it was defined as the sum of Ischemic Heart Disease (ICD Nos. 410–414), Hypertensive Heart Disease (ICD No. 402), and Cardiovascular Disease Unspecified (ICD No. 429.2) (See Appendices Tables 1 and 2).

Because there was no break in comparability for Acute Myocardial Infarction (MI) and Diseases of Heart between the two revisions those two categories were used to confirm the trends for CHD.[14] Acute MI, a category within CHD, was coded using category No. 410 during both revisions. Diseases of Heart, a more general category which includes CHD, was defined during the 8th Revision as ICDA Nos. 390–398, 402, 404, 410–429 and during the 9th Revision as ICD Nos. 390–398, 402, 404–429.

Statistical Methods

Linear regression was used to compare the slopes for both the *absolute* and *relative* rates of change in CHD mortality.[15–17] The *absolute* rate of change in CHD mortality was calculated as the change in the age-adjusted mortality rate/100,000 population/year. A log-linear model, which assumes that there is a constant proportional or *relative* change, was used to calculate the average annual per cent change.[17] Data for Figure 1 and Tables 1, 2 and 4 were calculated using the entire age range, and for Table 3 they were calculated only for people ages 35–74.

Because of the prior work that found evidence for a slowdown in the decrease in all cause mortality,[13] we anticipated that the slope or rate of decline in CHD during 1976–85 would be less than during 1968–75, i.e., that mortality rates for CHD decreased at a slower rate during 1976–

FIGURE 1—Trends in age-adjusted Coronary Heart Disease for all ages, United States, 1968–84.

85 than during 1968–75. But, since it is important to monitor any change in mortality trends a two-sided t-test was used in comparing the slopes from the two periods. Statistical significance was set at the 0.05 level with a critical t-value (df = 14) of 2.145. To examine the effects of our reclassification of CHD during ICD 9, the same procedures were used to compare slopes for the periods 1968–78 and 1979–85. However, because we were examining trends in CHD mortality over a relatively short period of time, we emphasize consistency in the data more than statistical significance.

To investigate the impact of our recategorization of the mortality data coded under the 9th Revision on the analysis of CHD trends, comparisons were also made using first the original 9th ICD classification for Ischemic Heart Disease (ICD Nos. 410–414) and then adding incrementally Hypertensive Heart Disease (ICD No. 402) and Cardiovascular Disease Unspecified (ICD No. 429.2) (Table 1). The values for either absolute or relative rate of change in CHD mortality were not changed by including the other two categories. Addition of Hypertensive Heart Disease and Cardiovascular Disease Unspecified to Ischemic Heart Disease minimized the discontinuity between the two ICD periods without affecting the trends during 1979–85.

Projected age-adjusted CHD mortality rates for 1985 were determined using the race-sex specific regression equations for 1968–75. Excess CHD mortality associated with the slowing up in the rate of decline after 1975 was estimated by comparing the observed and the projected age-adjusted rates for 1985. The observed age-adjusted rate minus the projected one divided by the observed was used to define the percentage excess in age-adjusted mortality. The excess number of CHD deaths in 1985 was calculated by multiplying the percentage excess in the age-adjusted rates by the observed number of CHD deaths for the year 1985.

Results

CHD mortality rates (age-adjusted) have declined in the US for all four of the major race-sex groups throughout 1968–85 (Figure 1). A break or leveling off in the trend lines for White females, and for Black males and females appears around 1976, while there is no discernible break or leveling off for White males. (The rises in mortality discernible in 1972–73 and 1980 are related to increases in CHD mortality during influenza epidemics.)

With Black males and females and White females, both the absolute and the relative rates of decline after 1975 were slower than during the period 1968–75 (Table 2). Black females experienced the greatest leveling off in CHD mortality in both absolute and relative terms, followed by White females, and then by Black males. White males did not experience a slowdown; in fact there was evidence of an increase in their rate of decline.

We replicated the analysis shown in Table 2 for ages 35 through 74 years (Table 3). The age-adjusted data for this restricted age range support the hypothesis of a slowdown in the rate of decline in CHD mortality after 1975 for White and Black females and Black males, although, the results for Black males, were not "statistically significant". Furthermore, results consistent with Table 2 were found when

age-adjusted trends for Acute MI and Disease of Heart were compared between 1968–75 and the 1976–85 (data available from authors).

Age-specific trends are also shown in Table 3. Black women experienced an absolute and relative slowdown across all age groups, while the slowdown among White women appeared to be present in only the older age groups. An absolute slowdown was present in all age groups for Black men, while the relative changes in CHD mortality do not follow a clear pattern.

The excess mortality associated with the slow down in CHD mortality rates is shown in Table 4. Black females had a mortality rate from CHD in 1985 that was 27 per cent higher than the rate projected from the 1968–75 trend; White females and Black males had rates that were approximately 10 per cent higher. Based on the percentage changes in age-adjusted mortality, there were an estimated 40,000 more CHD deaths for White and Black females and Black males in 1985 than there would have been had the 1968–75 trend continued. The majority of these deaths (30,000) were of White females.

Discussion

One of the more remarkable features of the decline in CHD mortality that began in the US in the mid-1960s was its virtually simultaneous onset and similar relative magnitude of decline in the four major race-sex groups, and across the entire age range where deaths from this disease occur.[1,2] The analysis presented here suggests that this pattern of decline began to change significantly in the mid-1970s and, although age-adjusted CHD mortality rates continued in a downward trend for each of the four demographic groups, the rapid rate of decline observed from 1968–75 has persisted only for White males.

Regardless of whether we classified deaths during 1979–85 to minimize the effect of changing from ICDA 8 to ICD 9, used 1979–85 or 1976–85 as the second time period, or used absolute or per cent changes, the results were the same. The rate of decline has not slowed for White males and has slowed for females of both races and to a lesser extent for Black males.

We do not believe that the divergence of CHD trends is a result of coding changes that were instituted in 1979 with the introduction of ICD 9. The divergence began around 1975–76, three years before the introduction of ICD9, and the trends for 1976–85 were very similar to those for 1979–85. Moreover, the results for all ages (Table 2) were similar to the results where the analysis was restricted to persons ages 35–74 years (Table 3). Finally, the same results were found for Acute MI and Diseases of Heart, two disease categories with no discontinuity between the two ICD periods.

The major difficulty in evaluating CHD trends in the US, in the absence of long-term community-based myocardial infarction registries, remains the validity of the death certificate.[19–23] We can find no evidence that secular trends over the last two decades have been influenced by significant changes in patterns of reporting cause of death by medical practitioners. More important is whether a systematic bias in reporting for the different race-sex groups[24] exists and has changed, or whether changes in the classification system alter the final code assigned. There is evidence, albeit less than satisfactory, that Blacks have a higher proportion of out-of-hospital deaths from CHD[25–28a] than Whites. Comparison of death certificate data and hospital admissions in at least three communities support this contention,[25–27] and findings from the pilot phase of the Community and Cohort Surveillance Project also suggest that a higher proportion of CHD deaths among Blacks occur out of the hospital.[29] It has also been demonstrated recently that the delay before receiving medical care during the acute phase of MI is longer among a group of Blacks seen at a large urban municipal hospital than previously reported for Whites.[30] None of these studies, addressed the issue of change over time in coding these deaths, however.

Why are the death rates from CHD no longer falling at the same rate for all the four race-sex groups? Any attempt to analyze the decline in CHD mortality must take into account changes in the incidence of the disease and case-fatality rates.[7] A variety of community-based studies have suggested that the major factor in the US CHD trends during 1968–80 has been the decrease in incidence.[20,22,31–33] However, recent reports have suggested that the incidence of MI, as estimated by hospital admissions, may have increased in recent years;[34,35] although this could be an artifact resulting from more people with acute MIs reaching the hospital alive. Conflicting evidence also exists about the improvement in acute case-fatality rates from MI and the long-term prognosis. Data from two community surveys in Minnesota[32,36,37] from the National Hospital Discharge Survey,[35] and from DuPont[31] suggest a fall in case-fatality rates, while summary data for hospitals in Boston[38] and the Health Insurance Plan of New York[39] suggest no change.

If the leveling off in CHD mortality which we have observed is a result of changes in the trends in incidence of CHD then this should be reflected in changes in the distributions of major CHD risk factors, such as serum cholesterol, overweight, hypertension, and cigarette smoking. The best sources of data on risk factor levels in the US population—the National Health and Nutrition Examination Survey (NHANES) and the National Health Interview Survey—are inconsistent.[8,10,40,41] Between the midpoints of NHANES I (1974) and NHANES II (1978), mean serum cholesterol levels were estimated to have decreased by approximately 3–4 mg/100 ml for White and Black men and Black women, and 1 mg/100 ml for White women.[10] During that same time period, the prevalence of overweight remained unchanged for Black and

TABLE 3—Change in Mortality Rates for Coronary Heart Disease† for Persons Ages 35–74 Years during 1968–75 and 1976–84: United States, 1968–85

White women and increased somewhat for Black and White men.[41] The prevalence of definite hypertension (BP ≥160/95 mm Hg and/or currently taking antihypertensive medication) during the period from 1974 to 1978 increased slightly (1–2 per cent) for White males and females and decreased by approximately 3–4 per cent for Black males and females.[42] Finally, between 1965 and 1976 rates of current smoking have decreased by 10 per cent for both Black and White men while there have only been small changes for Black and White women.[41]

Considering simultaneous changes in serum cholesterol, smoking, and blood pressure between 1974 and 1978 yields a somewhat different picture, however.[40] In this case, the impact of the changes in these three risk factors for persons ages 35–74 years was assessed by comparing the percentage decrease in observed CHD mortality between midpoints of NHANES I (1974) and NHANES II (1978) with the expected percentage change in CHD. The expected change in CHD mortality was estimated based on each individuals' levels of the three risk factors in both surveys by using a multiple logistic model derived from the Framingham data. The changes in risk factors explained 50 per cent or more of the observed decrease in CHD mortality between the two surveys. Thus, on a national level, small simultaneous changes in multiple risk factors can have important effects.

Other factors, such as competing cause effects and access to medical care, could alter these relationships. Additionally, such factors as economic trends and socioeconomic status or social class may also play a substantial role in changes in CHD mortality trends.[43–52]

Our purpose in this study was to document the divergence in CHD mortality trends and the slowing of the rate of decline for three of the four major race-sex groups in the United States. The public health importance of the slowing in rates of decline is evidenced by the approximately 40,000 excess CHD deaths of White females and Black males and females that would not have occurred if mortality rates had continued at the rates observed during 1968–75. The results emphasize the need for increased efforts aimed at primary and secondary prevention and access to appropriate treatment in Blacks and in White females, while maintaining and improving upon the gains already made in White males.

TABLE 4—Comparison of Observed CHD Mortality for all Ages in 1985 with Mortality Projected from Trends during 1968–75

		Age-adjusted Rate (per 100,000 Population)		Difference in Mortality	
Race	Sex	Observed	Projected	Rate (%)	Number of deaths
White	Males	204.4	210.1	−2.8	−8,327
	Females	96.6	85.9	+11.1	+29,973
Black	Males	222.7	199.5	+10.4	+3,000
	Females	136.4	99.8	+26.8	+7,496

Rural Hospital Closures May Harm the Elderly

The closure of rural hospitals may hold serious implications for the very old living in rural areas of the United States. According to a research study published in the July issue of the *Journal of Rural Health*, such closures could have a critical impact on the rural elderly. The study, sponsored by the National Center for Health Services Research (NCHSR), analyzed distances traveled for hospital care by rural area residents in New York State. Few residents in the 75+ age group traveled beyond the county line for care. Most were hospitalized locally. Only 18 per cent crossed a county line to get care, compared with 31 per cent of those younger than age 75. Overall, 29 per cent of the State's rural inhabitants went outside their home county for hospital care. Two-thirds of this group went to urban medical centers.

The study, entitled "Patterns of Travel for Rural Individuals Hospitalized in New York State: Relationships between Distance, Destination, and Casemix," was conducted by Christopher Hogan, PhD, a former researcher at NCHSR. Reprints of the study are available from NCHSR Publications and Information Branch, Parklawn Building, Room 18-12, Rockville, MD 20857. Tel: (301) 443-4100.

Physical Activity and Coronary Heart Disease among Asymptomatic Hypercholesterolemic Men

(The Lipid Research Clinics Coronary Primary Prevention Trial)

David S. Siscovick, MD, Lars G. Ekelund, MD, John S. Hyde, MD, PhD, Jeffrey L. Johnson, MPH, David J. Gordon, MD, PhD, and John C. LaRosa, MD

Abstract: We examined the relation between reported regular strenuous exercise or hard physical labor and the incidence of coronary heart disease (CHD) death and nonfatal myocardial infarction among 1,533 hypercholesterolemic men aged 35–59 years who were in the placebo group of the Lipid Research Clinics Coronary Primary Prevention Trial. The mean follow-up of the cohort was 7.4 years. The men were free of clinical heart disease at entry; men with an abnormal resting electrocardiogram or graded exercise test also were excluded.

Regular physical activity was not associated with the incidence of CHD (RR = .94, 95% CI = .68, 1.38) in this study population. Adjustment by the proportional hazards model for age, low-density lipoprotein cholesterol, smoking, family history of CHD, and occupation did not alter this finding. This observation suggests that reported regular physical activity may not be related to the risk of coronary heart disease among asymptomatic, hypercholesterolemic, middle-aged men. (*Am J Public Health* 1988; 78:1428–1431.)

Introduction

There is mounting evidence that regular strenuous physical activity is associated with a reduced risk of coronary heart disease,[1–4] but whether this relation applies to hypercholesterolemic men remains unresolved. Hypercholesterolemic men might particularly benefit from regular strenuous activity, if regular activity significantly altered lipoprotein levels[5] or mitigated their adverse effects. On the other hand, hypercholesterolemic men might benefit little or not at all from regular physical activity, if the cardiac benefits do not outweigh the risks of strenuous activity[6] in this subgroup.

We analyzed data from the Lipid Research Clinics (LRC) Coronary Primary Prevention Trial (CPPT)[7,8] to determine whether reported regular strenuous physical activity is related to the risk of coronary heart disease among asymptomatic hypercholesterolemic men.

Methods

Details regarding the design, implementation, and major results of the CPPT have been previously reported.[7,8] The CPPT was a double-blind, placebo-controlled clinical trial that tested the efficacy of lowering cholesterol levels with cholestyramine for the primary prevention of coronary heart disease (CHD). Twelve Lipid Research Clinics recruited 3,806 men, 35–59 years old, with primary hypercholesterolemia who were free of symptomatic CHD at entry. The men were required to have a plasma total cholesterol of 265 mg/dl (6.85 mmol/L) or greater (≥95th percentile) and plasma low-density lipoprotein cholesterol of 190 mg/dl (4.91 mmol/L) or greater at entry. Men with a plasma triglyceride greater than 300 mg/dl (33.07 mmol/L) or with type III hyperlipidemia were excluded.

Potential participants also were excluded from the trial if they had any of the following clinical manifestations of CHD:

- history of definite or suspect myocardial infarction;
- angina pectoris as determined by the Rose questionnaire;
- angina pectoris during submaximal exercise testing.
- various ECG abnormalities indicative of cardiovascular disease according to the Minnesota code: left bundle branch block, second or third degree heart block; two or more consecutive ventricular premature beats, left ventricular hypertrophy, R on T type ventricular premature beats, atrial flutter or fibrillation; or
- congestive heart failure.

Men with a positive exercise test result—ST segment depression or elevation of 1 mm or more—in the absence of other manifestations of CHD were not excluded from the CPPT.

Only men in good health and free of conditions associated with secondary hyperlipoproteinemia—diabetes mellitus, hypothyroidism, nephrotic syndrome, hepatic disease, hyperuricemia, and notable obesity—were included in the CPPT. Men also were excluded if they had moderate or severe hypertension—DBP ≥ 105 mmHg—or were receiving anti-hypertensive medication or had life-limiting or comorbid conditions such as cancer or non-atherosclerotic cardiovascular disease.

Participants were randomized into a treatment group that received cholestyramine and a control group that received a placebo; both groups were prescribed an identical moderate cholesterol lowering diet and attended Lipid Research Clinics every two months. Intervention by the clinic staff was restricted to the prescription of the study medication and the diet. The primary end-point for evaluating the treatment outcome in the CPPT was definite CHD death and/or definite non-fatal myocardial infarction.[7] All participants initially entered were followed up to the completion of the trial; the average length of follow-up was 7.4 years.

We restricted the present analysis to CPPT participants

in the placebo plus diet group (1,899 men) who underwent graded exercise tolerance testing at entry (1,897 men). Because we wanted to minimize the likelihood that subclinical CHD might distort the relation between strenuous activity and CHD, we excluded participants with other resting electrocardiographic abnormalities according to the Minnesota code (24 men), such as minor Q wave or ST segment changes, a positive graded exercise tolerance test (266 men), or a history of intermittent claudication (three men). Because of their small number, 71 men who were not White were also excluded. Thus, 80 per cent (1,533 men) of the original CPPT placebo group was included in the analysis.

We determined the level of each participant's habitual physical activity by the response to two questions asked to select a target heart rate for the baseline graded exercise tolerance test. The first question was, "Do you regularly engage in strenuous exercise or hard physical labor?" Participants who answered no to the first question were classified as inactive. If the answer was yes, the participant was then asked, "Do you labor or exercise strenuously at least three times a week?" Since 77 per cent of the participants who answered yes to the first question reported strenuous exercise or hard physical labor at least three times a week, participants who responded yes to the first question were classified as active. Eighty-two per cent of those classified as inactive based upon the baseline assessment reported that they did not engage in regular strenuous activity at each annual follow-up examination in years 2 through 7 of the CPPT.

We examined the validity of self-reported physical activity indirectly by demonstrating expected relationships with other factors—resting heart rate, graded exercise tolerance test performance, daily dietary caloric intake, and subjective rating of activity level outside of work—measured at screening visit 2. In addition, prior analyses from both the LRC Prevalence Study and the CPPT had demonstrated that self-reported physical activity based upon the response to the same two questions was related to plasma levels of high-density lipoprotein cholesterol.[9,10]

Factors that might confound the relation between regular strenuous activity and CHD also were assessed at entry into the CPPT. These included: total cholesterol, low-density lipoprotein cholesterol (LDL-C) (pre-diet), high-density lipoprotein cholesterol (HDL-C) (pre-diet), age, family history of heart disease, cigarette smoking, systolic blood pressure, Quetelet index, alcohol consumption, fasting plasma glucose, education, and occupation.

We examined the incidence of CHD death and/or nonfatal myocardial infarction (MI) in relation to the self-report of regular strenuous physical activity at entry into the CPPT. We also examined the relation between regular strenuous activity and CHD in a proportional hazards model that adjusted for baseline differences between physically active and inactive men in other risk factors at entry into the CPPT.

Results

We indirectly validated our assessment of physical activity in our analysis sample by demonstrating expected relationships with other factors, shown in Table 1. As expected, on the average active males had a lower resting heart rate and a lower heart rate at the end of the second stage of the graded exercise tolerance test, a longer graded exercise tolerance test duration, and a higher daily dietary caloric intake, and rated their activity outside of work as somewhat more than average, compared to inactive men.

TABLE 1—Validation of Reported Regular Physical Activity

	Active (N = 489)	Inactive (N = 1044)
	Means	
Resting Heart Rate (beats/min)	75	80
Graded Exercise Test		
Stage 2 Heart Rate (beats/min)	129	137
Total duration (sec)	615	572
Daily Dietary Intake (cal/kg)	30	29
Activity Outside Work*	2	3

*Based upon a subjective rating on a scale from 1 to 5; 2 = somewhat more than average, 3 = average.

The baseline characteristics of the men included in our analysis are shown according to their self-reported activity status in Table 2. As expected, active males had higher levels of HDL-C, were less likely to smoke, and more likely to engage in occupations that required manual labor, compared to inactive males. In addition, active males consumed more alcohol and were slightly more likely to have a family history of premature CHD. Total cholesterol, LDL-C, age, systolic blood pressure, Quetelet index, fasting glucose, and the proportion of college graduates were similar in the two groups.

The incidence of coronary heart disease death and/or nonfatal infarction was similar among active and inactive males (Table 3). Thus, physical activity was not related to the risk of CHD as reflected by our estimates of relative risk. Adjustment by the proportional hazards model for differences in the baseline characteristics and the length of follow-up did not alter these findings. In addition, our findings

Definite or suspect nonfatal myocardial infarction	14.6 (52)	15.0 (115)	

*A man experiencing a myocardial infarction and CHD death is counted once in this category; hence, this line is not the sum of the following two lines.

†After adjustment for age, smoking, LDL-cholesterol, family history of CHD, and occupation through use of a proportional hazards model, the relative risk = .98, 95% confidence interval = .68, 1.41.

were similar when we considered only men who reported strenuous activity at least three times a week as active.*

Examination of survival curves for combined fatal CHD and non-fatal MI according to baseline activity status confirmed the lack of an effect of reported activity on the risk of CHD during the entire follow-up period.* These findings were similar for fatal CHD and non-fatal myocardial infarction examined separately.*

Discussion

Our data suggest that reported regular strenuous activity or hard physical labor is not related to the incidence of CHD death and/or non-fatal myocardial infarction in asymptomatic hypercholesterolemic men. Although this finding may reflect a lack of effect, there are several alternative explanations that need to be considered.

First, misclassification of activity status might have obscured an effect of regular strenuous activity on the risk of CHD. We used a self-report of regular strenuous exercise or hard physical labor to characterize the level of habitual physical activity. The intensity, frequency, and duration of participation in specific types of physical activity were not measured. However, 77 per cent of the men in our analysis sample who reported some strenuous activity indicated that they regularly engaged in that activity for three or more times per week. In addition, we indirectly demonstrated the validity of self-reported activity in our study population. It is unlikely that the differences observed between active and inactive men in resting and graded exercise stage 2 heart rate, treadmill test duration, and HDL-C occurred by chance alone ($P < .001$ for each comparison). However, our analysis does not preclude the possibility of some misclassification, as suggested by the absence of larger differences between active and inactive men in these measures that indirectly reflect variability in strenuous physical activity. Nevertheless, we consider the self-report of regular strenuous activity or hard physical labor an indication that the man was physically active and not sedentary at entry into the CPPT.

Second, the statistical power of our analysis to detect an association between regular activity and CHD was somewhat limited, as reflected by the width of the 95% confidence limits for our estimates of relative risk. It is possible that we missed a decrease or increase in risk associated with regular activity of approximately 30 per cent, but it is unlikely that we missed the 50 per cent risk reduction demonstrated in previous epidemiologic studies of heterogeneous populations.[1–4] Furthermore, our best estimate of effect—the point estimate—suggests a very weak or no association between reported activity and CHD in our study population.

Third, males who were older, hypertensive, obese, or diabetic were excluded from the CPPT. Since we have previously suggested that males who are older, hypertensive, or obese might particularly benefit from activity,[11] these selection criteria might have influenced our estimate of effect. Nevertheless, we consider the presence of hypercholesterolemia, defined in the CPPT as a total cholesterol ≥ 95th percentile for middle-aged males, *the* major difference between our study population and those of previous studies.[1–4] For these reasons, our results are not directly comparable to those from other study populations, and it might not be appropriate to generalize our finding of no effect to persons with lower levels of plasma cholesterol and/or other CHD risk factors.

Regular strenuous activity has been suggested as an adjunct to the treatment of hypercholesterolemia.[12] In part, this recommendation is based upon the relationship between activity and HDL-C.[5] Active men had a higher plasma level of HDL-C at entry into the CPPT. The difference in HDL-C between active and inactive men was greater than that observed in exercisers versus controls in a one-year randomized study of the effects of exercise on plasma lipoproteins[13] and in a recent report from the Multiple Risk Factor Intervention Trial where leisure-time physical activity was inversely related to the incidence of first major CHD events and overall mortality.[14] Based upon the relation between HDL-C level and CHD in the CPPT placebo group, we might have expected active men to have an overall 10 per cent reduction in CHD.[15] Our analysis did not have adequate statistical power to detect an effect of this magnitude. However, it is also possible that the potential benefit of activity is balanced by the cardiac risks of activity in hypercholesterolemic men.

Our data suggest that reported regular strenuous physical activity may not be related to the risk of CHD among asymptomatic hypercholesterolemic middle-aged men. Thus, regular activity might not mitigate the effect of life-long hypercholesterolemia. For now, greater attention to other potential interventions that reduce the risk of CHD among hypercholesterolemic men[7] seems appropriate.

'Hospitals, Health Care Professionals and AIDS' Is Conference Theme

The American Society of Law & Medicine (ASLM), Public Responsibility in Medicine and Research (PRIM&R), and the Harvard AIDS Institute will hold a major national conference on "Hospitals, Health Care Professionals and AIDS" at the Boston Park Plaza Hotel, December 1-2, 1988.

The meeting will focus on such charged and troubling issues as: the ethical duty to care for AIDS patients; discrimination against health care providers and patients; financing care and reimbursement; research and clinical initiatives; the rights of AIDS patients to experimental treatment; infection control; screening of patients; HIV-infected surgeons.

At the conference, issues will be discussed by leading national speakers from the fields of clinical research, medicine, law, support groups for AIDS patients and bioethicists. Conference registrants will also have an opportunity to participate in topical workshops and plenary sessions during the two-day meeting.

For further conference and registration information, contact Robyn Carey, Assistant Director, PRIM&R, 132 Boylston Street, Boston, MA 02116. Tel: (617) 423-4112; or Sharon Paaso, Associate Director, ASLM, 765 Commonwealth Avenue, Boston, MA 02215. Tel: (617) 262-4990.

The Persistence of *Shigella flexneri* in the United States: Increasing Role of Adult Males

ROBERT V. TAUXE, MD, MPH, ROBERT C. MCDONALD, MD, NANCY HARGRETT-BEAN, PHD, AND PAUL A. BLAKE, MD, MPH

Abstract: The annual reported isolation rate of *Shigella flexneri* decreased from 1964 to 1973, but has remained constant since then at 1 per 100,000. Between 1975 and 1985, the median age of males from whom *S. flexneri* was isolated rose from 5 to 26 years. During this time, the isolation rate of *S. flexneri* rose more than five-fold among men, did not change in adult women, and decreased in children. By 1985, 23 per cent of reported *S. flexneri* isolates came from men aged 20–49. Increased male homosexual transmission of *S. flexneri* is a possible explanation for these findings. (*Am J Public Health* 1988; 78:1432–1435.)

Introduction

Shigella flexneri has been replaced by *S. sonnei* as the most frequently reported *Shigella* serotype in many industrialized nations.[1] In the United States, the number of reported *S. flexneri* isolates declined steadily from 1964 to 1973, and the proportion of *Shigella* isolates that were *S. flexneri* dropped from 60.6 per cent to 15.5 per cent.[2] This decline stopped in 1974, and the number of reported isolates of *S. flexneri* has remained nearly constant since. We reviewed national *Shigella* surveillance data from 1967 to 1985 to examine and explain the persistence of *S. flexneri* in the United States.

Methods

The national *Shigella* surveillance system, organized in 1963, reached full national participation in 1967; since then all states except California have contributed continuously.* It is a passive, laboratory-based surveillance system which receives weekly reports of isolates and accompanying demographic information from state health departments. Duplicate isolates are excluded. No clinical information is provided, and asymptomatic excretors are not distinguished from the acutely ill. It has been estimated that 5 per cent of *Shigella* infections are reported.[3] Reporting forms, coding and data management have remained constant since the inception of the system.

Because the specific serologic subtype is often not reported, we grouped serotypes as *S. flexneri* 1, (serotypes 1a, 1b, and 1 unspecified); *S. flexneri* 2, (2a, 2b, and 2 unspecified); *S. flexneri* 3, (3a, 3b, 3c, and 3 unspecified); and *S. flexneri* 4, (4a, 4b, and 4 unspecified). Age-specific isolation rates were calculated based on the annual 49-state US civilian population. City-specific data were derived from the county-based *Shigella* surveillance system, by using the counties included in the Standard Metropolitan Statistical Areas (SMSAs) of the 21 largest cities outside of California.[4]

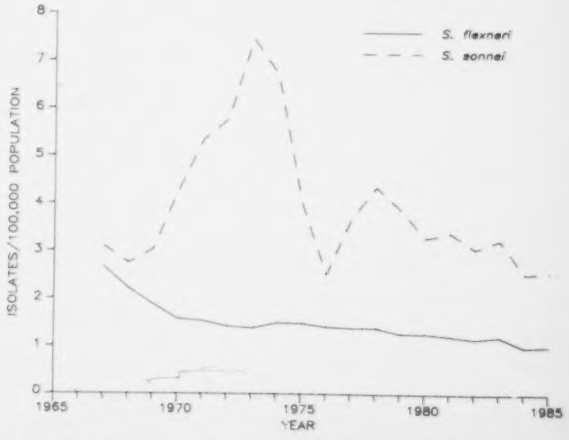
Tauxe, MD, MPH, Chief, Epidemiology Section, Enteric Diseases Branch, Division of Bacterial Diseases, Center for Infectious Diseases, 1-54 28, CDC, Atlanta, GA 30333. Dr. Hargrett-Bean and Dr. Blake are also with that division at CDC. Dr. McDonald, is an epidemiology elective student with the CDC Epidemiology Program Office, presently at the Department of Medicine, Washington University, St. Louis, MO. This paper, submitted to the Journal February 12, 1987, was revised and accepted for publication April 4, 1988.

*California did not report isolates between 1968 and 1973, and has not reported age-, sex-, or residence-specific data since then.

Results

The isolation rate of *Shigella flexneri* declined through 1973, and has been relatively stable since then at approximately 1 per 100,000 population (Figure 1). In the past, persons in custodial institutions and persons on Indian reservations have been at high risk for *S. flexneri* infections. However, the number of *S. flexneri* isolates reported from these groups has been decreasing, particularly from custodial institutions (Table 1). Although many isolates do not have a reported residence, these two groups accounted for only 5.9 per cent of all *S. flexneri* isolates for which a residence was reported during 1979–84.

A profound demographic shift in persons from whom *S. flexneri* isolates were reported began in 1976 (Figure 2). The reported age began to increase, particularly in males, whose median age rose from 5 years in 1975 to 26 years in 1985. This is the combined effect of a decrease in the age-specific isolation rates for children and an increase in the isolation rate among adult men (Figure 3). The greatest increase occurred among men 30 to 39 years of age. In this age group the isolation rate of *S. flexneri* climbed fom 0.26 per 100,000 in 1970 to 1.41 per 100,000 in 1985 (Figure 4). By comparison the isolation rate among women in the same age group did not change, and the rate among young children decreased substantially. The increase in median age among females since 1983 is the result of the decreased isolation rate among



*REPORTED TO THE NATIONAL SHIGELLA SURVEILLANCE SYSTEM, EXCLUDING CALIFORNIA.

TABLE 1—*S. flexneri* Isolates Reported from High-Risk Groups in the United States, by 6-Year Interval, 1967–84

Interval	No. *S. flexneri* with Residence Reported	Mental Institutions # Isolates	Mental Institutions (% of Total)	Indian Reservations # Isolates	Indian Reservations (% of Total)
1967–72	8257	3136	(38.0)	455	(5.5)
1973–78	6588	1029	(15.6)	515	(7.8)
1979–84	5726	72	(1.3)	264	(4.6)
1967–84	20571*	4237	(20.6)	1234	(6.0)

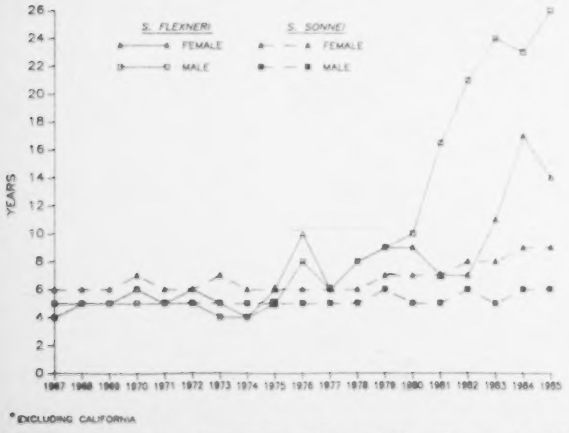
*Representing 29 per cent of all reported *S. flexneri*.

children, and not to an increase in the isolation rate among adult women. In 1970, 5.5 per cent of all reported *S. flexneri* isolates came from men aged 20–49; this proportion increased to 23 per cent in 1985.

These changes in age- and sex-specific isolation rates can be seen in the individual serologic subgroups of *S. flexneri*. The isolation rate of serogroup 1 among men increased sharply in 1980, without a similar increase that year among adult women (Figure 5). The other *S. flexneri* serogroups also show striking temporary increases among adult men without parallel increases among women or children: *S. flexneri* four in 1974, *S. flexneri* two in 1978, *S. flexneri* three again in 1983, and *S. flexneri* four in 1984.

The increase in *S. flexneri* isolations among adult men is particularly evident in large cities (Table 2). In the 21 largest cities in the United States outside of California, in the period 1967–72, isolates of *S. flexneri* from women 20–49 years of age equaled or outnumbered those from men of the same age in all but two of these cities. In the period 1973–78, isolates from men became more frequent, exceeded those from women in eight of these cities, and accounted for over half of all *S. flexneri* reported in the US in that age- and sex-group. In the period 1979–84, these trends continued, and isolates from men exceeded those from women in 16 of these cities.

In contrast, the median age of persons with *S. sonnei* has not shifted markedly (Figure 2). In 1970, men aged 20–49 years accounted for 8 per cent of isolates of *S. sonnei*, in 1985 this proportion was 10 per cent. In 17 of the 21 cities



*EXCLUDING CALIFORNIA

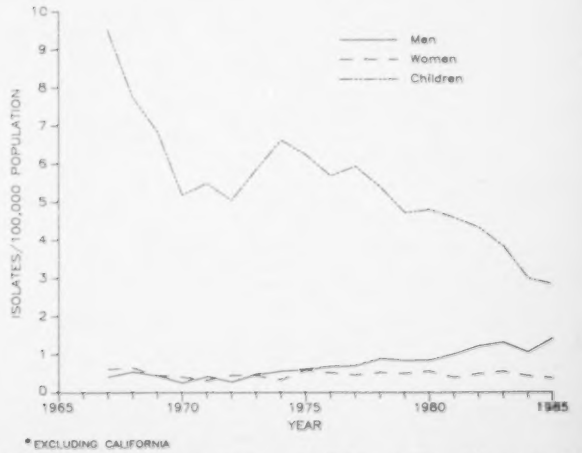
FIGURE 3—Age- and Sex-specific Isolation Rates of *S. flexneri*, 49 States, United States, 1970 and 1983

examined above, *S. sonnei* was isolated from more women than men aged 20–49 in the six-year period 1979–84. Sixty-three per cent of *S. dysenteriae* from persons ages 20 to 49 in 1967–72 came from men, 46 per cent in 1973–78, and only 44 per cent in 1979–84.

Discussion

Interpretation of national *Shigella* surveillance data is hampered by the limited information reported with each isolate, by regional variation in case ascertainment and reporting, and by changes in the delivery of medical care over time. However, laboratory methods for culturing and serotyping *Shigella* have changed little in the last 20 years, and the surveillance system itself has remained virtually constant since its inception. Internal comparisons suggest secular trends for the nation as a whole.

S. flexneri has persisted in the United States despite a steady decline in the rate of isolation from children, and a



*EXCLUDING CALIFORNIA

FIGURE 4—Isolation Rates of *S. flexneri* in Children less than 5 Years old and Men and Women Aged 30–39, 49 States, United States, 1967–85

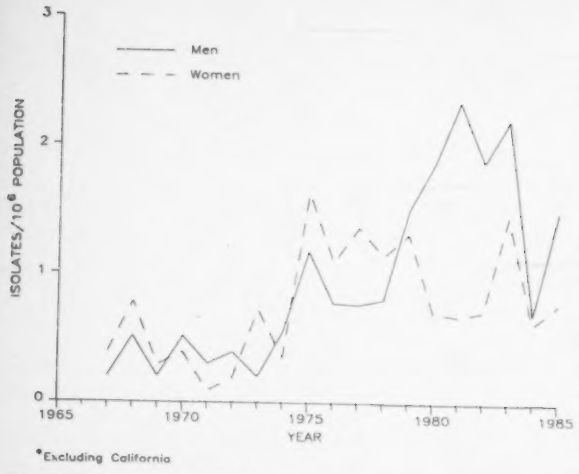


FIGURE 5—Isolation Rate of *S. flexneri* Serogroup 1 in Men and Women Aged 30–39, 49 States, United States, 1967–85

decrease in the number of reported isolates from Indian reservations, and custodial institutions. This persistence has been accompanied by a striking increase in the isolation rate among adult men; approximately one-fourth of reported *S. flexneri* isolates now come from adult men. In many large cities, infection restricted to adult men appears to have supplanted the traditional cycle of *S. flexneri* infections in children and their caretakers. Individual serogroups of *S. flexneri* have gained national predominance among adult men in a sequential fashion without similar increase in women or children. These observations suggest that the urban-dwelling man aged 20–49 is at particular risk for *S. flexneri*, and that transmission restricted to this group may explain much of the persistence of the serogroup.

There are several possible explanations for the increasing role of the adult male. Men may participate more in the care of ill children, but this would not explain selective increases in serotypes restricted to adult men. Men may travel more than women, although one might expect travel-associated shigellosis to represent a broad spectrum of serotypes, rather than successive waves of individual serotypes, and *S. dysenteriae*, a travel-associated serotype, is more frequent among women than men. An increase in the number of homeless men, particularly those discharged from mental institutions, may play a role, although *S. flexneri* has not been documented as a particular problem of the homeless. An increase in adult male immigration from Latin America to the urban United States is a likely but undocumented contributing factor. Male homosexual transmission is also likely to be an important factor, if *S. flexneri*, like other established homosexually transmitted diseases, has become common among young, urban male homosexuals.[5] The relative importance of these explanations cannot be ascertained from the national surveillance data.

Male homosexual shigellosis was first noted in San Francisco in 1974, the year that the national upward trend in *S. flexneri* isolates from men began.[6] In that city, *S. flexneri* 2a was initially predominant among male homosexuals, followed by *S. flexneri* 3a, and then *S. sonnei*.[7] In Seattle the following year, *S. flexneri* 3 was the predominant serogroup among male homosexuals and *S. sonnei* also appeared to be transmitted among male homosexuals; 30 per cent of all shigellosis reported in 1975 occurred in male homosexuals.[8] Among men with shigellosis at the New York Hospital in 1970–75, 58 per cent of those without recent travel were homosexual, compared to 10 per cent of those with recent travel.[9] By 1985, shigellosis in San Francisco was largely a disease of homosexual men: 82 per cent of all reported *Shigella* was *S. flexneri*, and 66 per cent of patients with shigellosis were homosexual or bisexual men.[10] The relative rarity of *S. sonnei* in San Francisco is curious, since this is by far the most common serogroup in the US, and raises the question of whether *S. flexneri* is more efficiently transmitted than *S. sonnei* by homosexuals. Although immunosuppressed adults may develop severe *Shigella* bacteremia, the effect of AIDS (acquired immunodeficiency syndrome) on *Shigella* transmission is not known.[11]

It remains to be established whether homosexual transmission explains the nationwide increase in *S. flexneri* isolations from adult men. If it does, reducing the incidence of these infections may require new control strategies, beyond emphasizing handwashing and food hygiene. The homosexual practices likely to transmit *Shigella* are oral-anal and oral-genital sex. Changes in the prevalence of these practices because of concern about AIDS could have some impact on *S. flexneri*.[6,8,12–14] In San Francisco, reported shigellosis decreased by 30 per cent from 1981 to 1985.[10] This decrease may be analogous to recent reports of decreases in rectopharyngeal gonorrhea in men in New York City,[15] and in gonorrhea in men in Denver,[16] and London.[17] However, the continued nationwide increase in *S. flexneri* isolations from adult men through 1985 suggests that such behavior changes are not widespread, or that non-sexual transmission among adult men is also important. In some areas, case-investigation of *S. flexneri* reported from men may help identify those in need of health education about AIDS.

TABLE 2—Reported *S. flexneri* Isolates from 20- to 49-year-old Persons by Sex in the 21 Largest United States Cities,* by Year of Report, 1967–84

OTA Special Report: Biology, Medicine, and the Bill of Rights

By effectively forcing people to make life and death decisions about themselves, about other people, and even future generations, the new genetic and medical technologies are raising questions about the meaning and scope of constitutional principles, according to a recent report from the Congressional Office of Technology Assessment (OTA).

Constitutionally, the central question becomes: would State regulation of these decisions impinge on some individual liberty that is guaranteed by the Bill of Rights? And, if so, is the individual's interest in exercising that right outweighed by the contrary interest of the State — considered to be the "public interest"?

Whether the government can or should regulate biotechnology is not an abstract question, according to Representative Robert W. Kastenmeier (D-WI) of the House Committee on the Judiciary. "It involves matters of birth and death, heredity and new life forms, disease and aging," he noted. In view of these and similar policy issues, he requested OTA to assess how the laws, institutions and scientific research might move forward together. This report is the result of that effort.

According to OTA, other decisions include the patenting of living organisms, using fetal tissues for research, human cell therapy, prenatal diagnosis and treatment, mandatory testing for genetic or infectious diseases, the right to treatment, and the right to refuse treatment. Is there a constitutional right to do research? Should there be areas of "forbidden knowledge"? What values should be reflected in federal research funding allocation and federal guidelines?

Some traditional public health practices — constitutionally long- established under State police powers — are almost certain to be challenged anew because of today's broader interpretation of individual rights of privacy and autonomy, according to OTA, This is occurring, for example, in the context of the AIDS epidemic with regard to mandatory reporting, contact tracing, mandatory testing, occupational or educational restrictions, and quarantine.

Improving the Life-Course Development of Socially Disadvantaged Mothers: A Randomized Trial of Nurse Home Visitation

David L. Olds, PhD, Charles R. Henderson, Jr., Robert Tatelbaum, MD, and Robert Chamberlin, MD

Abstract: We evaluated a comprehensive program of prenatal and postpartum nurse home visitation for socially disadvantaged women bearing first children. Eighty-five per cent of the participating women were either teenagers (<19 years at registration), unmarried, or of low socioeconomic status. Women were randomly assigned to either nurse home visitation or comparison services (free transportation for prenatal and well-child care and/or sensory and developmental screening for the child). During the first four years after delivery of their first child, in contrast to their counterparts in the comparison group, nurse-visited White women who had not graduated from high school when they registered in the study returned to school more rapidly; nurse-visited, poor, unmarried White women showed an 82 per cent increase in the number of months they were employed, had 43 per cent fewer subsequent pregnancies, and postponed the birth of second children an average of 12 months longer. (*Am J Public Health* 1988; 78:1436–1445.)

Introduction

In 1985 there were nearly 500,000 births to women under 20 years of age in the United States and over 800,000 to women who were unmarried, regardless of their age (12.7 per cent and 22.0 per cent of all births, respectively).[1] Adolescent and out-of-wedlock parenthood create substantial risks for both mothers and children. Adolescent mothers are in jeopardy of dropping out of school, having rapid successive pregnancies, and becoming dependent on welfare.[2–6] Children of adolescent mothers are more likely to be afflicted with a variety of health and developmental problems.[7–13] These maternal and child dysfunctions are even more likely to occur if an adolescent mother gives birth to a second child soon after the first.[4,5,14] Out-of-wedlock births create economic hardships and corresponding pressure on women to take low-paying jobs and/or to rely on Aid to Families with Dependent Children (AFDC).[15] Children born out of wedlock are also at risk for a host of problems,[16–19] but the extent to which those problems are due to the mother's single-parent status as opposed to poverty or young age is unclear.[15,20] Government expenditures on the sequelae of adolescent and out-of-wedlock childbearing are enormous.[21,22]

During the past 20 years, numerous programs have been developed either to prevent unintended pregnancy in these socially disadvantaged groups[23,24] or to reduce its consequences.[25–33] The effectiveness of many of these programs is obscurred, however, because of flaws with the evaluation designs.[34–36] Furthermore, many services for these groups fail to address the full array of stressful conditions with which socially disadvantaged parents must contend as they try to improve their life situations.

Even though it is common for visiting nurses to help new parents reduce unwanted subsequent pregnancies, return to school, and find employment, there are no studies that have examined the effectiveness of nurse home visitation as a means of improving maternal life-course development. The present study was established to test a comprehensive and intensive program of prenatal and postnatal nurse home visitation aimed at improving the outcomes of pregnancy, early childrearing, and life-course development of women who were either teenaged, unmarried, or poor, and bearing first children.

The program was based on the premise that nurse home visitors are in an optimal position to identify and help change factors in the family environment that interfere with maternal health habits, infant caregiving, and personal accomplishments in the areas of work, education, and family planning. In earlier papers we reported that the program improved the conditions and outcomes of pregnancy and reduced the incidence of caregiving dysfunction; many of the positive outcomes of the program were concentrated in families at highest risk for particular problems in these areas.[37,38] The intervention also was designed explicitly to promote maternal educational and occupational achievements and to reduce the number of subsequent unintended pregnancies. This paper evaluates the effectiveness of the program in these areas.

Methods

Research Design

The study design consisted of a randomized clinical trial. Participating families were assigned at random (details in Appendix) to one of the four treatment groups outlined in Table 1.

Treatment Conditions

Treatment 1—When the children were one and two years of age, an infant specialist hired by the research project screened them for sensory and developmental problems and referred those with suspected problems to other specialists

TABLE 1—Services Provided in Each of the Four Treatment Groups

Services Provided	Treatment Group 1 N = 90	2 N = 94	3 N = 100	4 N = 116
Sensory and developmental screening at the 12th and 24th months of life	+	+	+	+
Free transportation to regular prenatal and well-child visits		+	+	+
Nurse home visitation during pregnancy			+	+
Nurse home visitation during the first 2 years of life				+

for further evaluation and treatment. No services were provided through the research project during pregnancy.

Treatment 2—Families were provided free transportation for regular prenatal and well-child care at local clinics and physicians' offices through a contract with a local taxicab company, as well as the sensory and developmental screening outlined in Treatment 1.

Treatment 3—Families were provided a nurse home visitor during pregnancy, in addition to the screening and transportation services. The nurses visited families approximately once every two weeks and made an average of nine visits during pregnancy. Each visit lasted approximately 1 hour and 15 minutes.

Treatment 4—Families received the same services as those in Treatment 3, but in addition the nurse continued to visit until the children were two years of age. For six weeks following delivery the nurses visited families every week; from six weeks to four months they visited every three weeks; from 14 to 20 months they visited every four weeks; and from 20 to 24 months they visited every six weeks. Under predetermined crisis conditions, the nurses visited weekly. As during pregnancy, the visits lasted approximately 1 hour and 15 minutes.

Program Focus on Maternal Life-Course

Beginning during pregnancy, the nurses attempted to form an effective therapeutic relationship with the women by emphasizing the women's personal strengths. For example, the nurses:

- encouraged the women to clarify plans for completing their education, returning to work, and bearing additional children;
- stressed that the decision to return to school or seek employment after delivery should be made after fully considering what was in the women's own and their babies' best interests;
- helped interested women find appropriate educational and vocational training services and make concrete plans for child care;
- advised them in finding jobs and interviewing;
- showed the women and their partners birth control devices and discussed the advantages of different methods of family planning.

The discussions of family planning were carried out in the context of the women's desires for continued education, work, and achieving what they considered to be their optimal family size. When the women so desired, their husbands, boy friends, mothers, and other family members were encouraged to participate in the home visits. Families were also referred to other health and human services as needed.

The nurses used a detailed curriculum to guide their activities, but tailored the specific content of their home visits to the individual needs of each family. They refrained from imposing family planning methods on couples who had already decided that they wanted to have large families and their children spaced closely together.

Five registered nurses (none with baccalaureate degrees) were hired through a nonprofit private agency expressly for this experimental program. Before being assigned families in the experimental program, they participated in a three-month training program in which they each began working with two "pilot" families. Each nurse followed a caseload of 20–25 families from pregnancy through the child's second birthday. The nurses worked in two-person teams, with each member serving as a backup for her partner. By visiting one another's families at least once during both the pregnancy and the postpartum period, the members of the team were able to serve as ongoing supports for one another on a day-to-day basis. Detailed descriptions of the program are provided elsewhere.[39–42]

The Setting

The study was carried out in a small, semirural county of approximately 100,000 residents in the Appalachian region of New York State. At the time the study was initiated, the community was well served from the standpoint of both health and human services. In spite of this abundance of services, the community has consistently exhibited the highest rates of reported and confirmed cases of child abuse and neglect in the state.[43] Moreover, between 1967 and 1982 the number of manufacturing jobs in the area dropped from 17,400 to 9,000 (a 48 per cent decline)[44]; in 1981, the community was rated the worst Standard Metropolitan Statistical Area in the country in terms of its economic conditions.[45]

The Sample

Women were actively recruited if, at intake, they had no previous live births and had any one of the following characteristics that predispose to infant health and developmental problems: young age (<19 years); single-parent status; low socioeconomic status (SES). The study design nevertheless allowed the enrollment of any woman who asked to participate and who was bearing her first child. This avoided creating a program that was stigmatized as being exclusively for the poor; furthermore, by creating sample heterogeneity, it enabled us to determine whether the effects of the program were greater for families at higher risk. All women were enrolled before their 30th week of pregnancy. They were recruited through a free antepartum clinic sponsored by the health department, the offices of private obstetricians, Planned Parenthood, the public schools, and a variety of other health and human service agencies. Approximately 10 per cent of the target population was missed because of late registration for prenatal care. An additional 10 per cent was missed because some eligible women from the offices of private obstetricians were not referred. Between April 1978 and September 1980, 500 women were interviewed and 400 were enrolled. There were no differences in age, marital status, or education between those women who participated and those who declined. Eighty-eight of 442 Whites (20 per cent) declined to participate compared to two of 48 others (mostly Black). At registration, 47 per cent of the participating women were under 19 years of age, 62 per cent were unmarried, and 61 per cent came from families in Hollingshead's social classes IV and V (semiskilled and unskilled laborers).* Fifteen per cent of the women were not at risk according to the age, marital status, or SES criteria, and 23 per cent possessed all three risk characteristics.

The 46 non-Whites were excluded from the analyses reported here because this sample was too small to provide adequate subclass sizes when other factors of importance were included in the statistical model. The analysis of the non-White sample is presented elsewhere.[46]

*Hollingshead A: Four factor index of social status (unpublished manuscript), Yale University, 1976. Hollingshead's index was adapted slightly to accommodate the variety of household compositions found in our sample. Details of the procedure can be obtained from the first author.

Data Collection

The interviews that produced data for this report were carried out at registration (prior to the 30th week of pregnancy) and at the 6th, 10th, 22nd, and 46th months of the children's lives. Except in a small number of cases where women inadvertently disclosed their treatment assignments, all interviews were conducted by staff members unaware of the women's treatment.

Records from the county department of social services were reviewed by a social services employee (who also was unaware of families' treatment assignment) to determine the number of days that the women and their children received public assistance during the period from the index child's birth to fourth birthday. This review was carried out on women who were either unmarried, teenagers, or from social classes IV or V, for these conditions made them more likely to use public assistance; or whose interview data concerning public assistance use indicated that they had been recipients. Those cases in which women were believed to receive public assistance were treated as missing data if they moved out of the county for more than two months, even if partial public assistance data (based on the record review) were available. There were two exceptions to this rule:

- If the results of the record review indicated that the woman had been on public assistance for fewer days than indicated by her interview data, and she had moved out of the county during the interval under consideration, the woman's interview was used as the source of data.
- If the woman had temporarily moved out of the county and there was no indication of public assistance use before or after the move (from either the interview or record review), then 0 days on public assistance was entered as the outcome of our assessment.

Combining Treatments 1 and 2 for Analysis

Treatments 1 and 2 were combined for purposes of analysis after it was determined that there were no differences between these two groups in their use of routine prenatal and well-child care, the primary means by which transportation was hypothesized to affect outcomes. The combination of Treatments 1 and 2 is referred to hereafter as the comparison group. Treatment 4 is referred to as the nurse-visited (NV) group, or in the tables as "NV Pregnancy/Infancy." Treatment 3 is labeled in the tables as "NV Pregnancy" (nurse-visited during pregnancy). Estimates of treatment differences focused on the contrast of NV-Pregnancy/Infancy vs the comparison group for both the whole sample and those groups defined at risk. The statistical model and methods of analysis are discussed in the Appendix.

Results

Preintervention Treatment Conditions

Table 2 shows that before assignment to treatment conditions, the nurse-visited and comparison-group women were equivalent on all standard sociodemographic background characteristics. They differed, however, on some social support and psychological characteristics: In contrast to the women in the comparison group, there was a trend for the nurse-visited group to expect less accompaniment to labor and delivery; the nurse-visited unmarried women had a greater sense of control; and the poor, unmarried teenagers assigned a nurse reported receiving greater support from their boy friends. Because sense of control and husband/boy friend support were more consistently related to the outcomes of this study than was expected accompaniment to labor and delivery, the potential bias created by this initial nonequivalence was handled by including the first two variables in the statistical model as covariates.

Attrition

During the first four years after delivery, the women's rates of attrition varied from 15 per cent to 21 per cent (depending on assessment period) and there were no differences across treatments in the proportion of subjects with completed assessments. The nurse-visited women who discontinued the program, however, tended to have a greater sense of control over their lives than did those in the control group who discontinued. An examination of the reasons for these women's dropping out of the program indicated that they had either moved or miscarried. Because a larger number of women with greater sense of control discontinued in the nurse-visited group than did those in the comparison group, the preintervention treatment difference in sense of control for unmarried women was reduced in the sample on which 46th-month interviews were carried out.

Educational Achievement

Table 3 shows that among women who had not graduated from high school when they registered for the study, 59 per cent of the nurse-visited and 27 per cent of the comparison group had either graduated or had enrolled in an educational program by their 6th month postpartum. By the 10th month postpartum, the effect of the program held only for those women who had been unmarried at registration. There were no treatment differences in the proportion of women who graduated or remained in high school at the 22nd month postpartum, and there were no treatment differences by the 46th month postpartum in overall educational achievement.

Employment, Child Care, and Public Assistance

Table 4 shows that between birth and the 22nd month after delivery, nurse-visited, poor, unmarried older women had worked two and one-half times longer than their counterparts in the comparison group. By the 46th month postpartum, the nurse-visited, poor unmarried teenagers also had begun to work more than their counterparts in the comparison group, leading to an 82 per cent increase in the number of months worked by nurse-visited, poor, unmarried women (both teenagers and older) in contrast to poor, unmarried women in the control group. A qualitative analysis of the employment data revealed that at the time of the 46th month interview, most of the women who worked held unskilled labor and service positions; some held semiskilled jobs; a few were clerical and sales workers.

Table 4 also indicates that at both the 10th and 22nd month interviews, the nurse-visited, poor, unmarried teenagers reported greater concern about eventually finding employment than did the poor, unmarried teens in the comparison group, in spite of equivalent employment histories at those points in time. Among the poor, unmarried older women, those who were nurse-visited reported at the 22nd month interview less concern about finding employment.

At the 10th month postpartum, in contrast to their comparison-group counterparts, the nurse-visited, poor, unmarried older women reported that other family members helped them more with child care. During the first two years after delivery, the nurse-visited, poor, unmarried older women were on public assistance 157 fewer days than poor, unmarried older women in the comparison group (a 40 per

cent reduction); this effect, however, did not extend into the two-year period following the end of the intervention at the 24th month postpartum.

Subsequent Pregnancies

During the first 22 months after delivery, nurse-visited, poor, unmarried women had one-third as many subsequent pregnancies as poor unmarried women in the comparison group (Table 5). Between birth and 46 months postpartum, this reduction in number of subsequent pregnancies was present for the sample as a whole (for which there was a 23 per cent reduction), but as before it was concentrated among the poor, unmarried women (for whom there was a 43 per cent reduction). These differences in number of subsequent pregnancies were reflected in (nonsignificant) reductions in the number of births and spontaneous abortions, and in an interval between the birth of the first and second child that was an average of 12 months longer.

Discussion

During the first four years after delivery of their first child, nurse-visited women who had not completed their high school education at the time they registered in the study returned to school more rapidly than their comparison-group counterparts; and nurse-visited women who were poor and unmarried were employed 82 per cent more of the time, had 43 per cent fewer subsequent pregnancies, and delayed the birth of their second child an average of 12 months longer. The effects of the program on employment were conditioned by the age of the mothers and the period during which assessments of employment were carried out. During the first two years postpartum, the nurse-visited, poor, unmarried older women worked more than their counterparts in the comparison group, but the nurse-visited, poor, unmarried teenagers did not do so. The nurse-visited, poor, unmarried teenagers were more concerned about eventually finding work, however, and during the two-year period after the program ended, they began to work more than poor, unmarried teens in the comparison group.

With a program designed to respond flexibly to the individual needs of socially disadvantaged families, it makes sense that the positive effects of the program would depend on the families' circumstances. That the impact of the program on educational achievement would be greater among women who had not graduated from high school is consistent with the program plan, in that the nurses emphasized the importance of the young women at least completing their high school education. That the effect of the program was only temporary suggests that many young women sought employment as soon as they were old enough to do so, irrespective of what impact this might have on their long-term educational achievement. While many of the nurse-visited women apparently shifted their focus to earning a living, their counterparts in the comparison group caught up with them educationally.

Unmarried, poor women are at increased risk for welfare dependence once they bear a child,[22] so it is with this particular group that one would expect the program to have the greatest opportunity for improvement in employment status. It makes sense that the nurses' success in helping unmarried, poor women find employment would be conditioned by the women's age, because employment opportunities for adolescents were limited and because a substantial number were still trying to complete their high school education. The increase in number of months that the nurse-visited poor, unmarried teenagers worked during the two-year period after the program ended may be explained by their increasing age and their having returned to school more rapidly after delivery. It is worth noting (Table 4) that while the nurse-visited poor, unmarried teens worked more than their counterparts in the comparison groups, both groups worked more during the two-year follow-up period than they had during the first two years after delivery. The difference in employment probably was influenced by the reduction in number of subsequent pregnancies, although it also may be argued that the nurse-visited women's educational and occupational aspirations and achievements contributed to the prevention of repeated pregnancy.[5,48]

The marked reduction in subsequent pregnancy among poor, unmarried women is consistent with the nurses' efforts to prevent *unintended* pregnancy. Although the extent to which pregnancy is unintended among unwed women and adolescents is unclear,[49] it is more likely to be unintended in these groups than among older, married women.[50,51] From the available data, we are unable to determine the extent to which this reduction in subsequent pregnancy reflects in-

creased knowledge on the part of the nurse-visited women about how to prevent unintended pregnancy as opposed to their protecting their new prospects for educational and occupational achievement.

The presence of treatment effects concentrated on groups in greatest need in these areas is conceptually coherent, consistent with the program plan, and in keeping with at least one other intervention study addressing these issues.[28] The recent evaluation of Project Redirection, a national demonstration program aimed at helping young disadvantaged women attain economic self-sufficiency, found the strongest and most enduring effects to be concentrated among the most disadvantaged women.[28]

Several earlier studies also indicated that program effects on subsequent pregnancy, education, and employment disappeared within two to three years after the service ended.[23,28,29] In the current study, the corresponding pattern is mixed. For the sample as a whole, the impact of the program on subsequent pregnancy became stronger over time, while it began to diminish for the poor unmarried women. For those who had not yet graduated from high school, the influence of the program on educational achievement was short-lived; but for the poor, unmarried teenagers its impact on employment was not realized until after the program ended — once they became old enough to hold jobs.

Despite their coherence, these findings must be viewed with caution. Before the provision of services, the nurse-visited, unmarried women exceeded their comparison-group counterparts in sense of personal control, and the nurse-visited poor, unmarried teenagers exceeded their counterparts in boy friend support. Although we adjusted statistically for these preintervention differences, it is possible that there were other associated conditions that biased the sample in unknown ways. It should be emphasized, nevertheless, that this preintervention difference was attenuated because nurse-visited women with a greater sense of control discontinued the study more frequently than did their comparison-group counterparts. Moreover, no other preintervention differences were detected after a careful examination of the sample for a wide range of conditions that might bias relevant treatment contrasts.

Another reason for caution in interpretation is that the positive results of the current study were focused on specific at-risk subgroups. It may be argued that such findings have a greater chance of being sampling artifacts than do findings present for the sample as a whole. We do not subscribe to this interpretation, however, for two reasons. First, the effects detected for particular high-risk groups emerged from a series of planned comparisons incorporated in a set of statistical models that included factors (risk characteristics) identified at the stage of research design and used for sample recruitment (see Appendix). The second reason is the coherence of the findings.

There are a number of features of the present study that

[a]Variable constructed to estimate interval between first and second birth. Those women who had not given birth to a second child and were not pregnant at the 46th-month interview were assigned interval values as if they gave birth 9 months after the date of the interview. Those women who were pregnant with their second child at the 46th-month interview were assigned interval values on the basis of their expected date of delivery.

limit its generalizability to other programs and communities: First, the program was carried out under favorable circumstances. The nurses were hired and trained exclusively for this experimental program, and each nurse carried a manageable caseload. Second, the community in which the research was carried out is not representative of hard-core inner cities or extremely isolated rural communities. Third, although the women and children enrolled in this study do represent a substantial portion of the women and children in the United States, there are many to whom these results cannot be applied (e.g., Blacks, those who register for prenatal care after 30 weeks of gestation). Consequently, the present study should be replicated in other settings, with other populations, and under different administrative arrangements before its findings are used as a basis for major policy or program initiatives in this area.

Although the value of this kind of comprehensive program may be questioned on the basis of its impact on maternal life-course development alone, the potential cost-savings due to increased maternal employment and reductions in unintended pregnancy are substantial. Moreover, when considered from the standpoint of its simultaneous improvement of other aspects of maternal and child functioning, [37,38] it becomes a public health strategy worthy of careful consideration. Our results suggest that home-visiting nurses, working closely with parents and existing health and human service providers, may be able to produce demonstrable improvements in many aspects of maternal and child functioning that heretofore have been the province of several separate services. With augmented training, reasonable caseloads, and focused efforts, community health nurses could play a decisive role in reducing many of the risks and unfavorable outcomes associated with childbearing among poor, unmarried women.

APPENDIX

Treatment Assignment

Families enrolled in the program were stratified by marital status, race, and geographic region (based on census tract boundaries). These families were assigned at random to one of the four treatment groups. At the end of the intake interview the women drew their treatment assignments from a deck of cards. Separate decks were used for groups cross-classified by the women's race, marital status at intake, and for Whites, the geographic region in which they resided. To ensure reasonably balanced subclasses, the decks were reconstituted periodically to overrepresent those treatments with smaller numbers of subjects, a procedure similar to Efron's biased-coin designs.[52] (Women in Treatments 3 and 4 subsequently were assigned on a rotating basis, within their stratification blocks, to one of five home visitors.)

There were two deviations from the random assignment of women to treatments.

- First, in six cases, women who enrolled were living in the same household as other women already participating in the study. To avoid potential horizontal diffusion of the treatment in the case of different assignments within households, the six new enrollees were assigned to the same treatment as their housemates.
- Second, during the last six months of the 30-month enrollment period, the number of cards representing Treatment 4 was increased in each of the decks to enlarge the size of that group and to enhance the statistical power of the design to compare the effectiveness of the infancy home-visiting program with that of Treatments 1 and 2 as a means of improving postpartum outcomes. Analysis of selected outcomes confirmed that this slight confounding of treatments with time did not affect the pattern of treatment effects reported here.

The Basic Model and Methods of Statistical Analysis

Dependent variables for which a normal distribution was assumed were analyzed in the general linear model; dichotomous outcomes (such as educational status at 6, 10, and 22 months) in the logistic-linear model (assuming a binomial error distribution); and low-incidence outcomes in the form of counts (such as number of subsequent pregnancies) in the log-linear model (assuming a Poisson distribution).

A core model was derived consisting of a $3 \times 2 \times 2$ factorial structure: treatments (1 and 2 vs 3 vs 4) × maternal marital status (unmarried vs married) × social class (Hollingshead classes IV and V vs I, II, and III), with all interactions among these factors; two covariates measured at registration (maternal sense of control and reported husband/boy friend support) were included as well. Maternal age was also included in each analysis. For variables with assumed normal distributions, age was specified as a classification factor with two levels (≤ 18 years vs > 18), as were its interactions with the three other factors. In the generalized cases (binomial and Poisson), estimation was more stable in models with fewer subclasses. Age, in these cases, was specified as a covariate.

The analyses of dichotomous dependent variables measuring whether women had either graduated from high school or were currently in some kind of educational program were carried out in the sample limited to those women who had not yet graduated from high school at the time of registration in the study. The model specified treatments, maternal marital status, and their interactions as classification effects, and age and SES as additional covariates.

A thorough investigation in all models was carried out for each covariate to examine its interactions with categorical variables. Interactions between a covariate and one or more categorical variables (nonhomogeneous regressions) indicate that certain tests of means depend on the covariate, in that a different test exists for each covariate value. This investigation was undertaken both to ensure correct interpretations of mean differences and to examine any substantive findings resulting from the interactions between continuous and categorical effects.[53]

Estimates and tests were adjusted for all covariates, classification factors, and interactions. Analysis was by our own computer programs; iterative weighted least squares was used in the generalized binomial logistic-linear and Poisson log-linear models. The means presented correspond directly to the tests: they are equally weighted averages of the smallest-subclass means, adjusted for the covariates. In the generalized case the analysis is carried out and estimates obtained in terms of the linearized form of the model — the logits (or log of the odds) in the logistic models, and the logs of the incidence in the log-linear models. The tables show the estimates in this form for the log-linear case; in the logistic case the estimates are converted to odds for individual groups and to odds ratios for the treatment contrasts. Confidence intervals were derived from the variance of the estimates and are placed on mean differences, the odds ratios, and on differences of logs of the incidence. All statements of treatment difference in the text are based on 95 per cent confidence intervals; the term "trends" refers to 90 per cent confidence intervals. Also shown in the tables in the column labeled $\bar{X}$ is the transformation of these estimates to probabilities (for the logistic case) and to incidence (for log-linear cases).

We have reported the treatment main effects and the effects for poor unmarried women in those analyses that included treatments, social class, and marital status as the classification factors. The treatment effects are shown separately for the younger and older poor unmarried women in those analyses in which maternal age was added as a classification factor.

ACKNOWLEDGMENTS

This research was supported by grants from the Bureau of Community Health Services (HHS-MCJ-360403-07 and HHS-MCJ-363378-01-0), the Robert Wood Johnson Foundation (Grant Nos. 5263 and 6729), the W.T. Grant Foundation (Grant Nos. 800723-80 and 840723-80), the Ford Foundation (Grant Nos. 840-0545 and 875-0559), a Biomedical Research Support Grant (NIH) (PHS S7RR05403-25), and a Faculty Scholars Award from the W.T. Grant Foundation to the first author (Grant No. 861080-86). We wish to thank Karen Hughes, Janice Sheppard, and Elizabeth Bement for their help with preparation of the manuscript and processing of the data; Robert Cole, Gilbert Forbes, Howard Foye, Elizabeth McAnarney, Catherine Stevens, Sydney Sutherland, and Henry Thiede for helpful comments on the manuscript; and Elizabeth Chilson, Diane Farr, Georgianna McGrady, Jacqueline Roberts, and Lyn Scazafabo for their work with the families enrolled in the program.

HRSA Funds $4 Million Home Health Program

More than $4 million was recently awarded by the Health Resources and Services Administration to five states under an innovative program designed to help low-income persons avoid unnecessary hospitalization by receiving health care in the home.

Grants were awarded to the states of Hawaii, Mississippi, North Carolina, South Carolina, and Utah. The states will implement the program through a variety of community-based organizations, and must contribute $1 to the program for every $3 in federal funds.

The program is intended to demonstrate how a multidisciplinary team of health and social service providers can effectively prevent unneeded hospitalization. Program funds may be used to pay for skilled medical and related health services, including those of the physician.

For additional information, contact Mr. Sis at HRSA, US Public Health Service, Department of Health and Human Services, 5600 Fishers Lane, Room 14-43, Rockville, MD 20857. Tel: (301) 443-3377.

DTP Immunization Status and Tetanus Antitoxin Titers of Mexican American Children Ages Six Months through Eleven Years

PETER J. GERGEN, MD, MPH, TRENA EZZATI, MSHYG, AND HAROLD RUSSELL, PHD

Abstract: Data from the Mexican American portion of the Hispanic Health and Nutrition Examination Survey (HHANES), conducted in 1982–83, were analyzed for the number of diphtheria, tetanus, and pertussis (DTP) immunizations reported for Mexican American children 6 months–11 years of age and for levels of tetanus antitoxin titers in Mexican American children 4–11 years of age. In Mexican American children 6 months–11 years, 98.2 per cent had one or more DTP immunizations reported (95 per cent CI: 97.5, 98.9%); 85.1 per cent had three or more DTP immunizations reported (95 per cent CI: 83.2, 87.0%). The reported immunization coverage in Mexican American children was corroborated by the tetanus antitoxin titers which were above the minimum protective level (≥0.01 IU/ml) in 99.6 per cent of the 4–11 year olds. Using the American Academy of Pediatrics' (AAP) recommendations for the number of DTP immunizations, 61.1 per cent of the children 6 months–11 years of age had the age-appropriate number of immunizations (95 per cent CI: 58.5, 63.7%). AAP immunization completion rates were higher for children who: had a source of care reported (62.1 vs 44.3%; 95% CI of the difference: 7.1, 28.5); had insurance coverage (63.5 vs 56.1%; 95% CI of the difference: 2, 12.8); lived in a standard metropolitan statistical area (SMSA)-not central city as compared to SMSA-central city or not SMSA (66.6 vs 57.1%; 95% CI of the difference: 4.3, 14.7); and had 12 or more completed years of education for the head of the household (65.4 vs 58.3%; 95% CI of the difference: 1.8, 12.4). These four predictors were used to identify subgroups within the Mexican American population at high risk for incomplete immunization status. (*Am J Public Health* 1988; 78:1446–1450.)

Introduction

The health status and use of health care services by the Hispanic population in the United States have been questioned, because of the language barrier faced by many Hispanics and their lower income and education levels, relative to the general population.[1,2] To help clarify these issues, the National Center for Health Statistics (NCHS) conducted the Hispanic Health and Nutrition Examination Survey (HHANES) to assess some aspects of the health and nutritional status of the Hispanic population in selected areas of the United States.

In the HHANES, one surrogate measure of health care use was reported diphtheria, tetanus, and pertussis immunizations (DTP) and tetanus serology. DTP shots are given in connection with routine preventive care and thus reflect use of health care services. DTP immunizations, along with other childhood immunizations, have been identified as a 1990 Health Objective for the Nation.[3] Data from HHANES provide the first information on the attainment of this objective by Mexican-American children.

This paper focuses on the number of DTP shots reported in the Mexican American portion of the Hispanic Health and Nutrition Examination Survey (HHANES) for children 6 months–11 years of age and tetanus titer levels among children 4–11 years of age.

Methods

HHANES Survey Design

The HHANES was conducted among three Hispanic subgroups from July 1982 through December 1984 in three target areas of the United States: Mexican Americans in five southwestern states, Puerto Ricans in the New York City area, and Cuban Americans in Dade County (Miami), Florida.[4] The sample design of HHANES was a stratified, multistage, probability sample of persons 6 months through 74 years of age. Only data from the Mexican American portion of the survey are presented in this report.

The Mexican American portion of HHANES was conducted among civilian, noninstitutionalized persons of Mexican origin in parts of five southwestern states (Arizona, California, Colorado, New Mexico, Texas). The sample of 14 primary sampling units (PSUs), counties or small groups of counties, included 9,894 sample persons of whom 7,462 (75 per cent) were interviewed and examined. The weighted estimates presented in this report are representative of Mexican Americans in these five southwestern states. The weights for each survey participants included adjustments for nonresponse and noncoverage of geographic areas.

There were two levels of noncoverage of the Hispanic population in the southwest HHANES: 1) noncoverage of the Mexican American population residing in excluded counties in the Southwest with a small number and/or per cent of Mexican American residents (about 3 per cent); and 2) noncoverage of the Mexican American population residing in excluded census block groups or enumeration districts with small numbers of eligible Hispanics within the sample PSUs (about 10 per cent). Given the above two levels of noncoverage, the net coverage rate of the 1980 Mexican origin population in the Southwest was approximately 87 per cent.[4]

The sample weights were also post-stratified to Mexican American population totals for the Southwest as estimated by the US Bureau of the Census at the midpoint of the Mexican American portion of HHANES, i.e., March 1, 1983. Details of the HHANES sample design, selection process, operational plan, quality control procedures, and questionnaires have been previously documented.[4]

Data Collection

The HHANES included both a household interview and a three-hour medical examination conducted in a specially designed mobile examination center (MEC). During the household interview, information on children less than 12 years of age was obtained from the parents or other respon-

TABLE 1—Percentage of Mexican American Children 6 Months–11 Years of Age with Reported Diphtheria, Tetanus, and Pertussis Immunizations

Age (yrs)	Sample Size	Population Estimate (in 000's)	One or more DTP Immunizations	Three or more DTP Immunizations	AAP Recommendations for DTP Immunizations[a]
0.5–11	2,562	2,221	98.2 (97.5,98.9)	85.1 (83.2,87.0)	61.1 (58.5,63.7)
0.5–1	364	329	95.3 (92.3,98.3)	65.8 (59.0,72.6)	65.8 (59.0,72.6)
2–6	1,152	997	98.1 (97.0,99.2)	85.4 (82.6,88.2)	61.3 (57.5,65.1)
7–11	1,046	895	99.5 (98.9,100*)	91.7 (89.4,94.0)	59.1 (55.0,63.1)

a) American Academy of Pediatrics recommendations:
0.5–1 year—at least 3 DTP immmunizations;
2–6 years—at least 4 DTP immunizations;
7–11 years—at least 5 DTP immunizations;
( ) = 95% Confidence Interval
* = Rounding.
SOURCE: NCHS, HHANES, 1982–83

sible adult household member. Upon completion of the household interview, participants were scheduled for an examination that included tetanus antitoxin titers for children 4 through 11 years of age.

Study Population

A total of 3,000 children 6 months–11 years of age were selected for the Mexican American portion of HHANES; 85.4 per cent completed the immunization section of the household interview; 78.5 per cent participated in the examination.

In the 4–11 year age group, 2,027 children were selected for the survey: 84.7 per cent completed the immunization section of the interview; 78.2 per cent participated in the examination. Tetanus titers were measured in 70.6 per cent of the examined children 4–11 years of age. Failure to obtain an adequate blood specimen was the primary reason for not performing the tetanus titer assay. The children having tetanus antitoxin titers measured were slightly older than the interview and examination sample (mean age 7.9 versus 7.5 years); they did not differ, however, on any of the other variables used in this study.

Variables

Tetanus antitoxin titers were determined by the Immunology Laboratory of the Division of Bacterial Diseases, Center for Infectious Disease, Centers for Disease Control, using the hemagglutination assay method[5] as part of a collaborative project with the Division of Maternal and Child Health, Health Resources and Services Administration, and NCHS. A protective level of tetanus antitoxin titer was considered to be 0.01 IU/ml or greater.[6,7]

Age was reported as year of age at last birthday. Immunization histories were obtained by recall during the household interview; the protocol did not require verification of responses by the participant's shot record. A child was considered to be up-to-date on immunizations if he/she had received the number of DTP shots recommended by the American Academy of Pediatrics (AAP): 6 months–1 year, at least three DTP shots; 2–6 years, at least four DTP shots; 7–11 years, at least five DTP shots.[8]

Source of care referred to the reporting of a usual place where routine health care or treatment of illnesses was received.

The poverty-income ratio (PIR) was calculated by dividing the total household income by the poverty threshold for a household of that size. The poverty thresholds, published by the Census Bureau,[9,10] are based on the total income needed to maintain a household on a nutritionally adequate food plan. Of the 2,562 in the study population, 194 were missing data on the PIR and were excluded from the analyses of PIR.

Education was defined by the completed years of education for the head of the household. Of the 2,562 in the study population, 138 were missing data on education and were excluded from the analyses of education.

Residence was originally categorized in three ways: standard metropolitan statistical area (SMSA)-central city, SMSA-not central city, and not SMSA. Preliminary analyses found the rate of immunizations similar between SMSA-central city (57 per cent) and not SMSA (57.5 per cent). As a result, these two categories were collapsed in further analyses.

Statistical Analysis

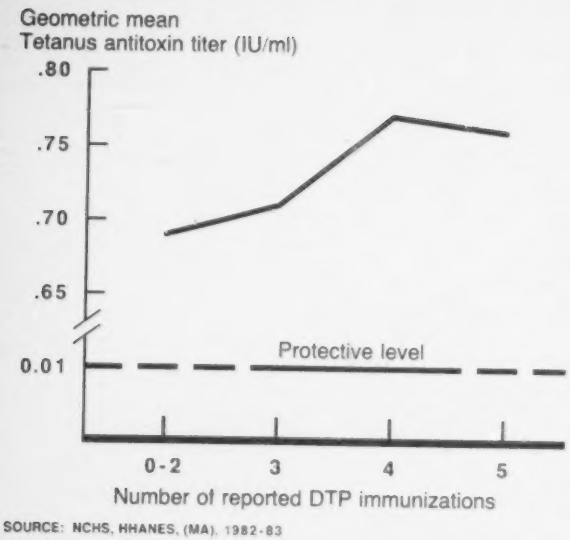
Sampling weights were used when calculating point estimates in order to account for individual selection probabilities and adjustments for non-response, non-coverage, and post-stratification which resulted from the complex survey design used in HHANES.

The complex survey design used in the HHANES tended to increase the variances which would have been obtained through simple random sampling.[11] The complex survey design was accounted for by using an average design effect to adjust the variances calculated under the assumption of simple random sampling. As described by Kovar,[12] the design effect is the ratio of the variance of a statistic from a complex sample to the variance of the same statistic from a simple random sample of the same size. The value of the design effect serves as an indication of the impact of the complex sample design on the variance. The average design effect for immunization status was 1.85. A t-test was used to compare point estimates and a linear test for trend was made using an orthogonal contrast.[13] All data analyses were done using programs accessible through SAS.[14]

Results

In Mexican American children 6 months–11 years of age, 98.2 per cent had one or more DTP immunizations reported (95% CI: 97.5, 98.9%); 85.1 per cent had three or more DTP immunizations reported (95% CI: 83.2, 87.0%) (Table 1).

This high level of reported immunizations is supported by the tetanus antitoxin titers of Mexican American children 4–11 years of age (Figure 1). Overall 99.6 per cent of Mexican American children had tetanus antitoxin titers above the



SOURCE: NCHS, HHANES, (MA), 1982-83

FIGURE 1—Tetanus Immunity Status of Mexican American Children four years through 11 years of age

minimal protective level of 0.01 IU/ml regardless of the number of DTP shots reported. A slight but unimportant increase in tetanus titers was noted with an increasing number of reported DTP shots. In the 4–11 year age group, 99.3 per cent had one or more DTP immunizations.

In the HHANES, using the AAP recommendations, as defined earlier, a more pessimistic picture emerges; 61.1 per cent of Mexican American children 6 months–11 years of age had up-to-date immunization coverage (95% CI: 58.5, 63.7%) (Table 1).

The association between various sample person characteristics and reported up-to-date immunization status according to AAP standards is shown in Table 2. Higher levels of up-to-date immunization coverage were found among children having a source of care reported, having health insurance coverage, living in a SMSA-not central city as compared with SMSA-central city or not SMSA, and with 12 or more completed years of education for the head of household. Higher levels of reported up-to-date immunization coverage were found in children living at or above the poverty level and those in families of four or fewer persons, however, these differences included 0 in the 95 per cent confidence interval of the difference. Little variation in up-to-date immunization coverage by sex was noted.

Four predictors of up-to-date immunization coverage were found in this study (source of care, health insurance, residence in a SMSA-not central city, and 12 or more completed years of education for the head of the household). These four variables were tested to see if they could be used to identify a segment of the population at high risk for incomplete immunization status (Table 3). When 0–1 predictors were present nearly 50 per cent of the children had incomplete immunization coverage. But when all four predictors of up-to-date immunization coverage were present, the percentage of children reporting incomplete immunization coverage dropped to 28.3 per cent.

Discussion

Virtually all 6 months–11 year old Mexican American children had at least one DTP immunization. The high level of immunization coverage found in HHANES may reflect the efforts directed at increasing immunization levels beginning with the 1977 US Initiative on Childhood Immunization.[15] As a result of this Initiative, all 50 states now have requirements for immunization at the time of entry to school.[16] All children in HHANES 6–11 years of age reported school attendance.

The tetanus antitoxin titers measured on 4–11 years old Mexican American children corroborated the high level of reported immunizations. The tetanus antitoxin titers reflect past tetanus immunization, since naturally acquired immunity to tetanus is virtually nonexistent in the United States, and the disease state itself does not confer immunity.[17]

Certain subgroups of Mexican American children, such as children of migrant workers, however, may not have been well covered in the survey. The rate of immunization may be lower for these subgroups than for those reported in the total Mexican American population.

The 1990 Objective for the Nation on Immunization Status sets as its goal at least 90 per cent of two-year-old children with their basic immunization series complete.[3] In Mexican American children 2 years of age, 76.4 per cent had received three or more DTP shots. Thus, in regard to DTP immunizations, Mexican American children in the Southwest are short of the 1990 Objective.

Data on childhood immunization levels were not collected in previous Health Examination Surveys. The only national data on immunization levels for a comparable time period are from the 1982 United States Immunization Survey (USIS), a supplement to the Current Population Survey.[18,19] These data, however, are not strictly comparable to the HHANES because of differences in survey methodology. Also, the USIS was a subsection of a survey dealing with labor force participation and not a health survey as HHANES was.

The data collected in the USIS was for two groups: the total sample and the record sample, a subgroup claiming to have based its reported immunization history on a shot record. The record sample was approximately 33 per cent of the total sample. The record sample was found to be more consistent with the state data.[20,21] The accuracy of the immunization levels reported in the USIS have been verified by comparing the results to state reports on immunization status of children entering school.

Comparison of the data from the USIS[22] with comparable age groups in the HHANES revealed somewhat confusing results. In the 1–4 year age group, 78.6 per cent of Mexican American children in HHANES had three or more DTP immunizations. In the 1982 USIS total sample, 70.6 per cent of White children and 48.4 per cent of children of Other Races had three or more DTP immunizations and in the 1982 USIS record sample 88.4 per cent of White children and 74.6 per cent of children of Other Races had three or more DTP immunizations. In the 5–9 year age group, 92.1 per cent of Mexican American children in HHANES had three or more DTP immunizations, while in the 1982 USIS total sample 79.3 per cent of White children and 63.4 per cent of children of Other Races had three or more DTP immunizations. In the 1982 USIS record sample, 95.1 per cent of White children and 87.0 per cent of children of Other Races had three or more immunizations.

Thus, in regard to DTP immunization status, the relative position of Mexican American children, based on HHANES data, in comparison to White children in the 1982 USIS changes depending on which sample is used. However, the

relative positive of Mexican American children in comparison to children of Other Races does not vary between the two samples.

Examining the percentage of Mexican American children with reported up-to-date immunization coverage according to the AAP recommendations reveals a more pessimistic picture. Only 61.1 per cent of Mexican American children were considered up-to-date by these standards. However, with the addition of one more immunization, 79.8 per cent would be up-to-date and with the addition of two more immunizations, 93.0 per cent would be up-to-date. Thus, only two visits would be required to bring over 90 per cent of the children up-to-date on their immunizations.

The predictors of immunization coverage among Mexican American children in this study are similar to previously identified predictors: use or contact with the health care system,[23,25] socioeconomic status, e.g., income[26,27] and education[26–29]; residency in a certain area[26,27]; and family size.[26,27,29]

Identifying high-risk groups is the first step in the primary prevention of disease. In Table 3 the effectiveness of four predictors of immunization status are shown. These

predictors can be used by health care providers to identify Mexican American children at higher risk for incomplete immunization coverage.

American Federation of Teachers to Participate in Immunization Awareness Program

The American Federation of Teachers (AFT) has joined with the national network of children's hospitals in efforts to arrest the decline in childhood vaccinations. As part of an immunization awareness program, the groups will disseminate information in inner-city areas that have low levels of immunization. Over the last decade, the immunization rates have declined among preschool children of immigrant, poor, and minority children, due primarily to the lack of knowledge in these populations regarding the value of vaccinations.

The program will provide information to parents so they understand how their children can be protected from the dangerous childhood diseases that can threaten unvaccinated children. Central to the effort is a new booklet, available in both Spanish and English, which was prepared through a grant from Lederle Laboratories. The booklet discusses the preventable diseases (polio, measles, mumps, rubella, pertussis, diphtheria, tetanus, and haemophilus type-B infections); tells parents where to get vaccines, how they are administered, possible side effects; and includes a checklist for keeping track of immunizations. The brochure also alerts parents to the availability of free vaccinations — encouraging families with financial hardship to contact the Children's Hospital National Medical Center in Washington, DC at (202) 879-4458 for more information.

Copies of the brochure can be obtained by sending a self-addressed, stamped envelope to AFT Order Department, 555 New Jersey Avenue, NW, Washington, DC 20001.

Drinking Water Source, Diarrheal Morbidity, and Child Growth in Villages with Both Traditional and Improved Water Supplies in Rural Lesotho, Southern Africa

STEVEN A. ESREY, PHD, JEAN-PIERRE HABICHT, MD, PHD, MICHAEL C. LATHAM, MD, DANIEL G. SISLER, PHD, AND GEORGE CASELLA, PHD

Abstract: This study examined the growth and morbidity rates of young children in relation to exclusive and non-exclusive use of improved water supplies in rural Lesotho, southern Africa. Data were collected for 247 children 60 months of age and under between July 1984 and February 1985 in 10 villages that had an improved water supply at least one year prior to investigation. Children whose families relied exclusively on the new water supply for their drinking and cooking needs grew 0.438 cm and 235 g more in six months than children whose families supplemented the new water supply with the use of contaminated traditional water for drinking and cooking. The difference in growth was greater among children over 12 months of age at the start of the evaluation than among infants. This may be explained partly by lower rates for *Giardia lamblia*, the most commonly identified pathogen in stools in older children. Among infants, similar rates of *Campylobacter*, the most commonly isolated pathogen among infants, may have prevented larger differences. Results suggest that improved drinking water supplies can benefit preschool children's health after infancy, but only if they are functioning and utilized exclusively for drinking and cooking purposes. (*Am J Public Health* 1988; 78:1451–1455.)

Introduction

The evidence for increased health benefits following improvements in the quality of drinking water is equivocal.[1] Young children in urban areas appear more likely to benefit from improved water supplies than young children in rural areas, perhaps because in urban areas drinking water constitutes a major source of exposure to pathogens, while in rural areas other sources of exposure may be more important.

In a previous study in rural Lesotho, southern Africa, improved water supplies were not associated with less diarrhea.[2] In a more recent health impact evaluation in Lesotho, children from villages that had access to an improved water supply had lower stool isolation rates for *Giardia lamblia* and *Escherichia coli*, but they did not have less overall diarrhea.[3] Growth among children from villages without an improved water supply was better than among children from villages with an improved water supply.[3]

Several factors[1,4] could account for the lack of more positive findings in these and other similar studies. One reason postulated, but never documented, is that the improved water supply was not the only water source used for drinking and cooking purposes. This study estimates the protective effect of exclusive versus non-exclusive use of improved water supplies on the prevalence of pathogens in stools, diarrhea rates, and growth of preschool children who resided in villages that had access to an improved water supply.

Methods

The study was conducted in Lesotho, which is a mountainous kingdom surrounded entirely by the Republic of South Africa. The country ranges in elevation from 1,500 to over 3,400 meters, with the majority of the population in the lowlands under 2,000 meters. Ninety per cent of the population (1.5 million) is rural despite increasing urbanization.

Ten villages were studied from July 1984 to February 1985, all of which received an improved water supply between 1967 and March 1983. They were representative of all the villages that received an improved water supply during this time in terms of size and geographic location. The villages were located in four districts that included 50 per cent of the rural population of Lesotho and were in the lowlands or foothills.

All villagers had access to a continually functioning tap or hand pump for at least one full year prior to data collection. The community taps or hand pumps, each of which served 100 people or less, were dispersed throughout the villages. Gravity fed springs, in which water passed through a silt box, supplied water to the taps. In the flatter areas, bore holes were dug when springs or other surface water was unavailable. Depth of the average bore hole was 50 meters, sometimes exceeding 100 meters. Over 90 per cent of the hand pumps installed are the Moyno pump.

Data used in these analyses were collected in three five-week periods: July–August 1984, the cold and dry season, October–November 1984, and January–February 1985, the warm and wet season. Of the 294 children, 1–60 months of age, enumerated during period one, 258 children were found during period 3 (87.3 per cent). Attrition was similar in both groups. Reasons for attrition were: 13 could not be accounted for, 10 were visiting out of the village, eight migrated to another village, parents of three children refused continuation in the study, and two died (one from each group). Finally, 11 children were dropped from the analyses because they never used an improved water supply, leaving a total of 247 children available for analysis.

During the first and third rounds, mothers were interviewed and children were measured for length and weight. The child's age in months at the start of the study was also taken from clinic cards and verified by use of a local events calendar.

Children were weighed and measured for length according to standard techniques,[5] using a portable CMS weighing

scale (25 kg × 100 g) and measuring board (130 cm × 1 mm), respectively. Intraobserver (0.005 cm^2 and 0.001 kg^2) and interobserver (0.003 cm^2 and 0.001 kg^2) measurement error rates were small.[6]

In order to estimate growth differences for all 247 children over the six-month period final length or weight for all 247 children was regressed on the initial value,[7–11] and residuals from these regressions were then used as the growth outcome in subsequent analyses. Residual analysis accounts for all the effects that influence a child's body size at the start of the evaluation when examining the determinants of growth that occurred only during the time of the evaluation. Residuals are independent of the initial value and may be positive or negative. The difference in residual values between the exclusive and mixed users reflect differences in six-month growth among children. Results were similar when final body size was used as the outcome, while controlling for initial body size.

During round 2, stool samples were collected from 123 children, and they were examined for bacteria, parasites, and viruses according to standard methods reported elsewhere.[3] During all three rounds mothers were asked to report on the presence or absence of diarrhea in their children in the previous 24 hours. We used the common word "letsollo" in Sesotho, which means "running stomach."

Dummy variables related to use of water and socioeconomic conditions were constructed from the interview data. Children were classified according to whether the family relied exclusively on the improved water supply for their drinking and cooking needs (exclusive users) or supplemented the improved water supply with traditional water sources (mixed users). This information was obtained by interview during round 1. Children were also classified according to the family's per capita use of water drinking rounds 1 and 3. Changes in the quantity of per capita water use between rounds 1 and 3, increased versus decreased water use or no change, were also included in the analyses. Changes in per capita water use was a better predictor of growth than was per capita water use at either round 1 or round 3.[3]

Other potential confounding variables were included in the analyses. The dummy variables were village of residence, remittance from at least one person working in the Republic of South Africa (no, yes), latrines (no, yes), maternal literacy (no, yes), maternal marital status (no, yes), pregnancy (no, yes), frequency of maternal bathing (four or more times per week versus fewer than four), child's sex (male, female), child's age (1–12, 13–24, 25–36, 37–48, 49–60 months), and current breastfeeding (no, yes). Continuous variables were natural log of major household expenditures, number of pieces of agricultural equipment, number of major household possessions, household size, crowding (people/room), and parity. Some factors were kept as continuous variables because they explained more of the growth than if they were categorized.

Statistical analyses were done in SYSTAT, version 3.0,[12] a general linear program for least squares analysis of multivariate data. The child was the unit of analysis, and the variables listed above were included in the multivariate models. Ninety-five per cent confidence intervals were calculated. The effects on weight and length were adjusted for potential confounding by first including all factors above and then by including all factors except the effects due to changes in the amount of water used over seasons. Calculations of nutritional status of children compared to National Center for Health Statistics (NCHS) reference data were done using CASP, a software package from the Centers for Disease Control.[13] Length and weight gain, in separate analyses, were examined by comparing the odds ratio of being in the upper versus lower 25th quartile of growth for mixed and exclusive users.

Results

Of the 247 children, 125 were exclusive users and 122 were mixed users. Most potential confounders were distributed similarly between the two groups (Table 1). Three variables (remittance, maternal literacy, and crowding) were more prevalent among the exclusive users; they all were associated negatively with growth. Breastfeeding was also more common among exclusive users, but this was associated positively with growth only among infants. Frequent maternal bathing and increased water use were more common among mixed users; these factors were associated positively with growth. The percentage of exclusive users within each village was variable, ranging from 17.6 to 90.3.

Weight and length were similar between exclusive and mixed users at the start of the study (Table 2). Because initial body size and growth among children aged one, two, three, and four years was similar, only the combined effects of children 13–60 months of age at the start of the evaluation are reported. Mild malnutrition (low weight-for-age) in both groups was a result of stunting (low height-for-age), not wasting (low weight-for-height). In early infancy children followed the NCHS 50th percentile, but by the end of infancy they were already stunted and had lower weight-for-age

TABLE 1—Means of Potential Confounding Factors among Study Children by Use of Drinking Water

Factors	Exclusive Users (n = 125)	Mixed Users (n = 122)
Village of Residence	%	%

		Weight for Height		
1–12	33	110.4 ± 11.2	26	108.7 ± 9.4
13–60	92	100.4 ± 7.9	96	98.8 ± 8.3

values. Children within 13–60 months of age maintained their growth at about 88–89 per cent of the reference weight-for-age and 93–94 per cent of the reference length-for-age; wasting was not apparent.

Absolute unadjusted growth over the six-month period was similar between groups among the infants, but was greater among exclusive users compared with mixed users among the older children (Table 3). The difference in six-month growth between groups based on absolute growth or residuals was also similar. Only differences in six-month growth residuals between groups are presented below.

The average unadjusted difference in weight gain between exclusive and mixed users was 118 g (Table 4). Among infants, the unadjusted difference was inconsequential, but among children 13–60 months of age, the difference was 156 g. On average exclusive users also grew 0.236 cm more in length than mixed users (Table 5), 0.244 cm more among older children.

After adjustment for confounding, the weight gain of children was better among exclusive users than among mixed users whether or not the effects of changes in water quantity were controlled (Table 4). Exclusive users gained 235 g more than mixed users when changes in water quantity were controlled and 226 g when it was not controlled. The difference in length gain between exclusive and mixed users of the new water supply was 0.438 cm when water quantity was controlled and 0.404 cm when it was not controlled (Table 5). Among older children the effects were somewhat

Total	118 (−2,238)	235 (77,394)	226 (66,386)

†All variables listed in the methods section were controlled.

larger for weight and length gain when changes in water quantity were controlled than when it was not controlled; among infants the effects were smaller. When the odds ratio of being in the upper versus lower quartile was examined, mixed users were twice as likely to be in the lowest quartile than exclusive users for both length and weight gain.

In a subsample of 123 children in this study, stool isolation rates were 33 per cent lower for *G. lamblia*, 53 per cent lower for enteropathogenic *E. coli*, and 49 per cent lower for coronavirus-like particles among exclusive users compared with mixed users (Table 6). These pathogens were more common among older than younger children. *Campylobacter* was only slightly less common among infants in the exclusive group compared with the mixed group and *Giardia* was rare in infancy. Rotavirus, *Salmonella* and *Shigella* were not detected. Diarrhea rates were reported to be generally higher among exclusive users than mixed users (Table 7), but differences between groups were small except among infants during round 1.

Discussion

In summary, exclusive use of improved water supplies for drinking and cooking was associated with better child growth, depending on the child's age. Source of drinking water made virtually no difference among infants; among one- to four-year old children, it did affect growth. By extrapolation, the expected improvement in growth over the first five years of life would be 4.4 cm and 2.3 kg.

Comparison groups were similar in that only children from villages with an improved water supply were included in the analyses, thus removing any biases due to systematic differences between villages with and without improved water supplies. Exclusive users still grew less well, however, than children from non-improved villages,[6] even though they grew better than mixed users. Improved and unimproved villages were similar in rurality, village size, presence of schools or clinics, age and sex distribution, and general standard of living. Still, selection bias in the comparison of villages with and without improved water supplies cannot be ruled out, even though virtually all villages applied for a water supply. For instance, water supplies were constructed deliberately in villages that had a recent outbreak of disease.

In the comparison of exclusive and mixed users within villages with improved water supplies, uncontrolled differences may have existed such as distance to the tap or number of people for each tap. Those households nearest to the tap

13–60 months	40	10 (25.0)	49	24 (49.0)

or hand pump may have been different from the mixed users in resources or attitudes toward health, allowing them to be exclusive users. For example, these households may have had substantial influence in the village, thereby securing not only the power to determine where the new supplies were located but also the ability to mobilize limited resources that also fostered better child growth. Energy intakes between exclusive and mixed users also were not controlled and cannot be ruled out as a potential confounding effect.

The classification of exclusive versus mixed users was done by maternal reporting, not by observation. No incentive was apparent for mothers to report mixed use if they were in fact strictly exclusive users. On the other hand, mixed users may have reported exclusive use since engineers told villagers that the improved water supply should be used solely for drinking and cooking purposes and not for domestic hygiene. If such misclassification did exist, the differences reported above would be underestimated.

Improved water supplies were continually functioning and available for use during the time of the study and for at least one year prior to the study, with three exceptions:

- Prior to data collection one tap from one village had not been working for several weeks. It was reported and fixed prior to data collection.
- Water flow from improved supplies was limited occasionally either because of inadequate source water or because of volunteer restriction from the villagers themselves. In some instances, the taps were shut down for several hours in the middle of the day. Since most water in Lesotho was usually collected during morning and evening hours,[2] the midday closure of these taps probably did not explain differences in patterns of use.
- In another village, one tap was broken for several months and was not fixed. Ten children came from families that lived near this tap and did not use alternative improved water supplies elsewhere in the village. In yet another village, a child was not allowed to use the tap because the family did not contribute with either labor or to a general maintenance fund while receiving the improved water supply. These eleven children were excluded from the analyses because they may have been different from the other children. They gained less in weight but more in length than either the exclusive or mixed users.[6]

Possible reasons for the lack of more positive results among infants was the finding of *Campylobacter* almost solely among infants and the similar isolation rates among both groups. On the other hand, among older children higher isolation rates of *Giardia lamblia*, particularly among mixed users, may have accounted for part of the growth differences between groups. The association between coronavirus-like particles and diarrhea has not been adequately demonstrated, but the lower rate of coronavirus-like particles among exclusive users may have contributed to better growth.

Reported diarrhea rates were actually higher among

TABLE 7—Diarrhea Rates among Children 1–60 Months of Age at the Start of the Study by Use of Drinking Water

Children's Age in months	Exclusive Users		Mixed Users	
	n	Number (%)	n	Number (%)
Period 1

13–60	87	5 (5.7)	90	3 (3.3)

exclusive users, but reporting was subject to recall bias, defined by the mother, and not verified by clinical examination or observation. The growth variables, on the other hand, were measured with minimal error and not subject to misreporting.

Among infants growth differences between exclusive and mixed users were greater when per capita water use was not included in the analyses and virtually disappeared when water use was controlled, suggesting that among infants, use of water for cleanliness is probably more important than is clean drinking water, probably because virtually all infants were breastfed. The reverse was true among older children. Water quality may become more important as the protective effect of breastfeeding is removed.[14]

Larger villages tended to have a lower percentage of exclusive users than smaller villages. If village size, number of people per tap, or distance to taps was large, continued use of contaminated supplies may have occurred. The installation of more taps closer to individual homes might perhaps avoid the use of contaminated supplies and foster the exclusive use of the improved water supplies for drinking and cooking purposes.

Previous reports in Lesotho[2,3] indicate that improved water supplies must be coupled with health education to encourage people to use only the improved water supplies for drinking and cooking purposes. These supplies must also be maintained to ensure continual functioning, a crucial requirement often missing in water supply projects. Future studies of health impacts from improved water supplies should measure factors affecting water use such as distance to tap, number of families per tap, and reliability of the operation of the new or improved water supplies.

NEHA 53rd Annual Educational Conference: Call for Abstracts

The National Environmental Health Association (NEHA) has issued a call for abstracts for its 53rd annual educational conference to be held in Seattle, Washington June 24-29, 1989. The conference theme — The Nineties: A Decade for Change — will focus on the rapidly changing technologies and methods used to safeguard the public health from environmental threats. Special features of the conference will include:

- A computer software exchange featuring the latest innovations in software for the environmental health professional
- Two pre-conference seminars dealing with asbestos removal and the offering of a food certification examination
- A special all-day theme session dealing with public relations and the environmental health/protection professional

NEHA — a professional society composed of environmentalists from all areas of the field, including public and private sectors and academe — invites abstracts for papers to be presented at the June conference. Interested participants should submit a typed one-page abstract outlining the proposed presentation. The deadline for submissions is November 30, 1988.

For further information, contact Mel Monkelis, conference manager, NEHA, 720 S. Colorado Boulevard, Room 970 South Tower, Denver, CO 80222. Tel: (303) 756-9090.

Seating Position in Cars and Fatality Risk

LEONARD EVANS, DPHIL, AND MICHAEL C. FRICK, MA

Abstract: Fatality risk in passenger cars according to seating position (front versus rear; left versus center or right) was examined using Fatal Accident Reporting System (FARS) data for 1975 through 1985. Comparing the fatality risk of unrestrained occupants matched in sex and age (within three years) revealed effects attributable to seating position, and not to occupant characteristics correlated with use of different seats. Fatality risk to drivers was the same as fatality risk to right front passengers to within 1 per cent; this was so for crashes in all directions and for frontal crashes. Fatality risk in rear seats was (26 ± 2) per cent lower than in front seats, and lower in center compared to outboard seats by (22 ± 4) per cent for front seats and (15 ± 4) per cent for rear seats. The center rear seat was associated with the lowest fatality risk. (*Am J Public Health* 1988; 78: 1456–1458.)

Introduction

A car driver's physical environment differs from that of a front seat passenger because of the location of vehicle controls, especially the steering wheel. However, it is not known whether the driver or right front seat passenger is at greater injury risk. One of two analyses[1] found drivers less likely to be injured, while the other analysis found no difference. There are even larger differences in physical environment between the front and rear seats, and lower fatality risk has been associated clearly with the rear seat positions.[2]

A major problem in comparing safety of the driver and right front seating positions is that they tend to be used by occupants with systematically different probabilities of fatality in crashes. For example, right front passengers are disproportionately female, and females are more likely than males to be killed in crashes of the same severity.[3] Similarly, fatality risk depends strongly on occupant age.[3] The potentially confounding effects of sex and age are in fact larger than any anticipated fatality risk differences attributable solely to seating position. Attempts to remove such large confounding effects through multivariate analyses are unlikely to be satisfactory when the effect of interest is small compared to the confounding effects.

We therefore used a matched-pair analysis[4] to estimate the risk in various seating positions relative to that in the driver seat (hereafter referred to as the relative risk), using data from the Fatal Accident Reporting System [FARS][5] for 1975 through 1985.

Method

Data were selected from the Fatal Accident Reporting System (FARS), a computerized data file maintained by the National Highway Traffic Safety Administration containing detailed information on all traffic crashes occurring in the United States since January 1, 1975 in which anyone was killed.[5] Adult (age ≥ 16 years) occupants of passenger cars were selected from the FARS data for 1975 through 1985; occupants coded as using any type of restraint were excluded. Those with restraint use coded as unknown (about 30 per cent of all the data) were retained, even though about 4 per cent of these probably used belts.

The relative risk of fatality, R, to a passenger in some specific seat to that of the driver in the same car was estimated by confining comparisons to those cases in which driver and passenger were the same sex, the same age (within three years), and neither was coded as restrained.[4] That is

$$R = \frac{N_P}{N_D}, \qquad (1)$$

where N_P and N_D are the numbers of passengers and drivers killed, respectively, in cars containing drivers and passengers (in the specific seat being investigated).

By assuming that the observed fatality frequencies arise from a Poisson process, we estimated the standard error, ΔR, in R as

$$\Delta R = R\sqrt{1/N_D + 1/N_P}. \qquad (2)$$

Because the interpretation of R as relative fatality risk is essentially assumption free, there was no need to include an extra term reflecting possible systematic, or instrument-like, errors, as was done in earlier work (see, for example, equation 14 of Ref. 6 or equation 5 of Ref. 4).

Results

Figure 1 shows that for cars containing a driver and a

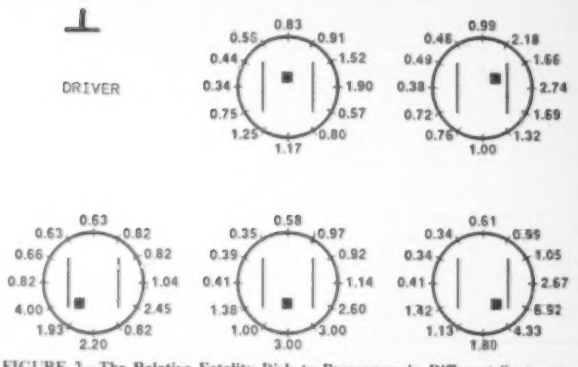

FIGURE 2—The Relative Fatality Risk to Passengers in Different Seats as a Function of Principal Impact Point
NOTE: The values shown are calculated in Table 1, which also provides the raw data

right front passenger, there were 15,880 right front passenger fatalities compared to 15,793 driver fatalities, for a right front passenger relative fatality risk of 1.006 ± 0.011. The center front seat R = 0.78 ± 0.04 indicates that this position was associated with a (22 ± 4) per cent lower fatality risk than the front outboard positions. This substantial difference probably reflects protective effects from the outboard occupants in the form of impact cushioning and ejection prevention.

The outboard rear seats were associated with lower fatality risk than the corresponding front seats. The relative risks in the two outboard positions did not differ, and may be combined to give a composite value for rear outboard seats of R = 0.739 ± 0.015. That is, for unrestrained occupants in outboard seating positions, rear seats were associated with a fatality risk (26.1 ± 1.5) per cent lower than for front seats. Comparing the center rear seat relative fatality risk of R = 0.626 ± 0.030 to R = 0.739 ± 0.015 for the rear outboard seats reveals that the fatality risk in the center rear seat was (15 ± 4) per cent less than in the rear outboard seats.

Table 1 shows data in the five passenger seating positions versus principal impact point, as coded in FARS in terms of clock points from 1 to 12. Although damage at, say, clock point 12 o'clock, may arise from the front of the vehicle being struck at an oblique angle, a principal impact point at 12 o'clock typically indicates frontal crashes. Table 1 shows the number of passengers killed for crashes with the indicated principal impact point divided by the number of driver fatalities for the same principal impact point. A high value of R may reflect an increased passenger fatality risk or a decreased driver fatality risk, or some combination of these. The seating locations follow the same representations as in Figure 1—a bird's eye view of the vehicle from above. The data were more concentrated at 3, 6, 9 and 12 o'clock than at adjacent clock points; these specific values will be discussed below. The values of R in Table 1 are shown schematically in Figure 2.

For principal impact point 12 o'clock, which may be interpreted approximately as indicating head-on impact, the value of R for right front passengers was R = 0.988 ± 0.019. Thus the similarity of fatality risk to drivers and right front passengers applies also to the frontal case.

In frontal crashes the advantage of rear compared to corresponding front seating positions was larger than for all crash directions combined. By comparing rear to front fatality risk in the left, center, and right seating positions, we found reduced risks in the rear of 37, 30, and 38 per cent, respectively. In comparing the results for frontal crashes only (12 o'clock in Table 1 and Figure 2) to those for crashes in all directions (Figure 1), we found that the frontal crashes were associated with a larger fatality reduction for rear seat compared to front seat occupancy, but a diminished reduction was associated with center compared to outboard occupancy. Both these findings are consistent with intuitive understanding of crash processes. The finding that there was still a reduced fatality risk in the center front (R = 0.83 compared to R = 1 and 0.99 in the outboard positions) and center rear (R = 0.58 compared to 0.63 and 0.61 in the outboard positions) may reflect some sideways occupant motion even for principal impact point at 12 o'clock, with the center occupant receiving cushioning and ejection protection from the outboard occupants.

For principal impact point at 6 o'clock, generally a rear impact, occupants in rear seats faced considerably higher fatality risk than those in front seats. Combining data for all three rear seats (Table 1) gives R = 142/68 = 2.09 ± 0.31; so occupants in rear seats were (109 ± 31) per cent more likely to be killed than were drivers. Despite this large difference, Table 1 shows that only a small fraction of rear seat occupant fatalities were due to rear impact. This is because rear impact crashes tend to be of low severity, even though there are many such crashes; typically, rear impact results from "fender-bender" types of two-car crashes in urban traffic, whereas a typical fatal crash is a single car impacting a fixed object, such as a tree, at high speed.

For principal impact point at 3 o'clock, passengers seated on the right side of the vehicle were at much greater risk than the driver. The relative risk was similar for front seat passengers (R = 2.74 ± 0.10) and rear seat passengers (R = 2.67 ± 0.24), for a weighted average value of 2.73 ± 0.09. Independent of whether they were seated in front or rear, occupants on the left side of the vehicle were subject to similar fatality risk (R = 1.04 ± 0.13 for the left rear passenger compared to R = 1 for the driver). Center occupants, whether

in front or rear, were more at risk than drivers in right impacts. Being in a right outboard position compared to being in a left outboard position increases fatality risk by (173 ± 9) per cent.

For principal impact point at 9 o'clock, the nominal indication was that the left rear passenger was at lower risk than the driver (R = 0.82 ± 0.7). If clock points 8 (with an anomalously high value of R), 9 and 10 are combined, the result becomes R = 0.94 ± 0.06, which indicates that the fatality risks to driver and left rear passenger do not differ in left impact crashes. The risk in left impact was substantially less for passengers in right seats than in left seats, but as in the corresponding situation for right impact, there was no indication that in a left side impact there was any difference in fatality risk between the right front (R = 0.38 ± 0.02) and right rear (R = 0.41 ± 0.04) seating positions. In right side impacts, 3,095 right front passengers were killed compared to 2,244 drivers killed in left side impacts, suggesting 38 per cent more impacts of high severity from the right than from the left.

For left side impacts, the driver relative to passenger fatality risk (that is, 1/R) was 2.60 ± 0.10 for front seat passengers and 2.46 ± 0.22 for rear seat passengers, for a weighted average of 2.58 ± 0.09; that is, the near side occupant was (158 ± 9) per cent more likely to be killed. This may be compared to the corresponding result of (173 ± 9) per cent for the right impact case. The quantitative agreement for these physically symmetric cases, and the general qualitative agreement found between many of the above results and physical intuition, adds credibility to the method and to confidence that the quantities used were coded with satisfactory reliability in the FARS data.

Discussion

The finding that the fatality risk to right front passengers was the same as that to drivers, to within about 1 per cent, was surprising in view of the substantial differences between the physical environment of drivers and right front passengers.[7,8] The similarity of fatality risk applies also to head-on crashes. Results apply only to fatality risk, and may not apply to other levels of injury. Large numbers of data permitted more precise estimates than have previously been available, and the close agreement of estimated risks for physically symmetric crashes lends credibility to the methods and data used. The estimates reflect the mix of cars and crash types included in the 1975 through 1985 FARS data. Another study[9] using the same method found that, for cars of model year 1966 and earlier, the right front passenger fatality risk exceeded that of the driver by (9.6 ± 6.5) per cent, whereas for cars of model year 1968 and later, the right front passenger fatality risk was (2.8 ± 2.0) per cent less than that for the driver.

Although all the results presented were for unrestrained occupants, it was possible to estimate relative fatality risk to restrained occupants in outboard seats using published estimates of restraint system effectiveness in preventing fatalities in outboard seats.[10,11] Taking lap/shoulder belt effectiveness[10] as (43 ± 3) per cent gives the relative fatality risk for occupants (necessarily outboard) using such systems as 0.57 ± 0.03. Taking lap-only belt effectiveness[11] for outboard rear seats as (18 ± 9) per cent gives a relative fatality risk to lap-belted outboard rear occupants of 0.739 × 0.82 = 0.61 ± 0.07, which, when the error limits are taken into account, is not different from the value for outboard front occupants. Hence, when all occupants use the most commonly provided restraint systems, no difference is indicated in the fatality risk to front or rear outboard occupants.

Examining relative fatality risk according to direction of impact showed that occupants closer to the point of impact were at much greater risk of fatality than those further from the point of impact. It must be remembered that these are relative risks and not absolute risks. For example, rear seats have lower overall fatality risk notwithstanding their high relative fatality risk in rear crashes because such crashes are so small a fraction of all fatal crashes (see Table 1).

Sunlight and Other Risk Factors for Cataracts: An Epidemiologic Study

GWEN W. COLLMAN, PHD, DAVID L. SHORE, PHD, CARL M. SHY, MD, DRPH, HARVEY CHECKOWAY, PHD, AND ALAN S. LURIA, MD

Abstract: A case control study was conducted in North Carolina to explore the relation between individual exposure to sunlight and the risk of cataracts. One hundred thirteen cases and 161 controls aged 40–69 at diagnosis were studied. Sunlight exposure was inferred from interview data on residency and time spent in the sun, combined with solar radiation data from the National Climatic Data Center. Sunlight exposure was very slightly related to all types of opacities combined. Although the numbers of cases with each type of opacity was small, the risk of cataracts was slightly increased in medium and high exposure categories for persons having cortical or posterior subcapsular opacities only, but not nuclear sclerotic changes. Persons with dark brown or hazel eyes are at increased risk. An unexpected finding was that persons who reported using tranquilizers for six months were at increased risk. (*Am J Public Health* 1988; 78: 1459–1462).

Introduction

Throughout the world, cataracts are most prevalent in areas where the amount of annual and daily sunlight is high[1–3] ambient temperatures are warm,[4] and the latitude is low.[3] These areas receive more solar radiation, which includes ultraviolet and infrared radiation and visible light.

Environmental measures of solar radiation exposure have been used in previous studies as surrogates for individual levels of sunlight exposure. In addition, these studies have relied on a single estimate of exposure, based either on current[2,4] or usual residence.[5] Such measures cannot correctly estimate the amount of sun exposure an individual receives, since lifestyle factors influence the amount of time spent in the sun within a geographic area, and since sun exposures change over the subject's lifetime.

To investigate this question further, we conducted a case-control study in North Carolina which utilized a detailed estimate of sunlight exposure for each study subject.

Methods

Study Population

All study subjects were selected from the patients of a private ophthalmology practice in Asheboro, North Carolina. During their first visit to the practice, each patient received a full ocular examination including both external and internal examination of the eye. Direct visualization of the lens using a Zeiss slit lamp was performed after pupil dilation (using 2 1/2 per cent Neosynephrine and 1 per cent Mydracil). All were examined by a single ophthalmologist (ASL).

Cases and controls were chosen by reviewing medical records of all patients aged 40–69 years old at their first examination (1980–83) (n = 864). Ineligible patients included those who were blind (before detection of an opacity), deceased, or did not have a working telephone number listed in their medical record. Cases who had cataracts removed by another physician were excluded because characteristics of the lens were not available. Controls were excluded if they had photokeratitis (a corneal burn due to high solar exposure).

Patients were considered to be cases if their chart indicated the presence of cortical, posterior subcapsular or nuclear sclerotic changes of the lens in either one or both eyes. Ophthalmic information abstracted from the cases' records included: type of cataract, severity of the opacity, number of opacities, eyes involved, surgery, visual acuity and comorbid ocular conditions. Cases were included regardless of visual acuity; and diagnoses were not validated in any other way. There were 133 cases identified in the population, 15.4 per cent of persons aged 40–69 years. Cataract type was classified separately for subjects with one type of opacity and multiple types of opacities. Patients with either one opacity in one eye or the same type of opacity in both eyes were classified in the single opacity type group. Multiple opacities either in one or both eyes were classified according to the combination.

Controls were selected from the remaining patients in the targeted age group. Their records showed no indication of opacification of the lens of either eye during the time of the study. Two controls similar to the cases with respect to current age (± two years) and sex were chosen, when available, otherwise one control was selected. One hundred and ninety-three controls were enrolled into the study.

Eighty-seven per cent (n = 283) of eligible subjects responded to the telephone interview, which gathered historical information on exposure to natural sunlight, demographic characteristics, ophthalmic factors, use of selected medications with photosensitizing properties, medical conditions, selected occupations, smoking, alcohol use, and caffeine intake. Few study subjects were Black (n = 9), so the analysis was restricted to the 113 White cases and 161 White controls.

Sun Exposure Measures

The variable for sun exposure was derived from various sources of questionnaire information. A complete residential history, from place of birth to current residence, was obtained for each study subject. For all residences of one year or more, the subject was asked the state and number of years of residency. The respondent was also asked to estimate the amount of time spent in the sun during those years. Subjects were given a choice of three responses (much time in the sun, a moderate amount, or a little time in the sun). Up to eight residences were recorded for each participant.

Mean total solar radiation values for each state were obtained from the National Climatic Data Center[6] which has

routinely measured daily direct and diffuse solar radiation on a horizontal surface at weather reporting stations in each state over a 47-year period (1915–62), although not all weather stations had been in operation for the full 47 years. An average solar value was calculated for states with more than one reporting station. Intensity of the solar radiation is measured in Langley units which equal one gram calorie per square centimeter.

An individual's average annual sun exposure was a weighted average of lifetime sun exposure. The radiation intensity of each state was multiplied by the duration of time spent in that state times the reported amount of time spent in the sun (assigned a proportionate value of 80 per cent for much time in the sun, 50 per cent for a moderate amount of time, 20 per cent for a little time in the sun). This product was summed over the various states of residence and divided by the respondent's age.

Statistical Methods

Unconditional logistic regression models were fitted with lens disease as the dependent variable and with the matching factors (age and sex) included in all models. The exposure variable, annual sunlight exposure, was included in various models as a continuous variable, dichotomized at the median value of the distribution or grouped into three categories (low, medium, and high). Screening procedures were used to identify potential confounders. Odds ratios and 95% confidence intervals were estimated from the logistic models. Separate models were fitted for each type of lens opacity with enough cases.

Results

As shown in Table 1, approximately 60 per cent of the study population was female. The majority of the cases and controls were elderly, non-diabetic lifelong residents of North Carolina.

Seventy-four per cent of all cataract cases had a single opacity type, as seen in Table 2. Nuclear sclerotic changes and posterior subcapsular changes predominated. Most cataract cases had opacities in both eyes, and few had greatly impaired visual acuity.

The mean annual sun exposure score was 212.40 Langley/year (SE=7.63) for cases and 207.62 Langley/year (SE=5.82) for controls. The average number of hours spent in the sun per day as an adult was 5.0 hours/day for cases and 4.9 hours/day for controls.

TABLE 2—Ophthalmic Characteristics of the Cataract Cases

Characteristics	Number (%)
Cataract type	
Single opacity	
Cortical	9 (8)
Posterior Subcapsular	13 (12)
Nuclear Sclerotic	56 (50)
Other	5 (4)
Multiple opacities	
Cortical & Posterior subcapsular	4 (3)
Cortical & Nuclear Sclerotic	3 (3)
Posterior Subcapsular & Nuclear Sclerotic	22 (20)
Number of Eyes Involved	
Unilateral	29 (26)
Bilateral	84 (74)
Number of Opacities—Right Eye	
0	14 (12)
1	83 (74)
2	16 (14)
Visual Acuity—Worst Eye	
20/25 or better	43 (39)
20/30—20/40	21 (19)
20/50—20/90	23 (21)
20/100 or worse	24 (21)

As presented in Table 3, for all types of opacities combined, the odds ratios were 1.06 for moderate exposure and 1.12 for high exposure compared with low exposure to sunlight. The number of cases with each type of opacity was small and the odds ratios correspondingly unstable. Sunlight exposure appeared to relate to cortical and posterior subcapsular opacity but not to nuclear sclerotic lens changes. These small changes in risk were also apparent when the sun exposure data were treated as continuous or dichotomized at the median.

Additional variables were examined as potential risk factors for cataract, as seen as Table 4. The use of tranquilizers was positively associated with the risk of lens opacities (OR=2.20, 95% CI=1.10, 4.39), with 15 per cent of the total study population reporting having used tranquilizers for at least six months. The type of tranquilizers used and frequency and duration of their use was not ascertained during the interview. Persons with hazel and brown eyes had higher risk than persons with green, blue and grey eyes. Persons who reported a family history of cataracts had a slightly increased

risk of lens disease. Diabetes, sunglass use, eye injury, and current smoking habit had odds ratios close to the null. A history of outdoor work which may involve higher sunlight exposure was not related to an increased risk of lens disease in either men or women.

Discussion

To our knowledge, this is the first case-control study conducted to estimate the risk of lens disease according to exposure to natural sunlight. Cases had a slightly higher mean annual sun exposure score than controls but reported an equal number of hours spent in the sun as adults. Our study showed a very weak increase in the overall risk of opacities as lifetime exposure to the sun increased. An increasing trend was seen for risk of cortical or posterior subcapsular cataracts but not nuclear sclerotic cataracts, as well as cases having a combination of opacity types, but these estimates are imprecise because of the small number of cases of each type. The very modest increase in risk we observed is smaller than previously reported from ecologic studies. Hiller, *et al.* [5] using HANES data, reported a risk ratio of 1.58 for Tucson, Arizona compared with Albany, New York. Studies done in Nepal[4] found a prevalence ratio of 2.6 for villages with 12 hours of sunlight compared with villages with 7–9 hours of sunlight. Similar patterns have been reported within Australia[2,7] and the United States.[3] Another study found more cataracts in Manila than in Tampa, Florida and Rochester, New York.[8] Additional analysis of the HANES data found exposure to ultraviolet-B radiation to be significantly associated with cortical changes (RR=3.6, n=55).[11] A positive association was found for nuclear sclerotic cataracts (RR=1.4, n=104) and a negative one for posterior subcapsular changes (RR=0.3, n=18). One likely reason for lower risk levels in these data is that 65 per cent of the study population were lifelong residents of North Carolina and therefore the range of exposure scores was narrower than in the nationwide sample.

Our risk estimates may also be biased toward the null because of limitations in the characterization of lifetime exposure. Solar radiation measurements for the state of residence were quite accurate, but the duration of residence and amount of time spent in the sun could have been incorrectly remembered or interpreted differently among study participants. No direct validation of this exposure classification scheme was possible, but we did note that the average annual sun exposure scores were higher for persons working outdoors than indoors (270.13 Langley/yr, SE=7.1 versus 194.37 Langley/yr, SE=5.0), and persons reporting greater than the median number of hours in the sun had higher scores than persons spending less time outdoors (245.35 Langley/yr, SE=5.6 versus 168.40 Langley/yr SE=5.6).

Our estimates of the relative risk of each of the individual cataract types require cautious interpretation because of the study size. We restricted our study population to ages 40–69 at age of diagnosis to separate the etiologic effects of solar radiation and aging and to improve recall, but there are fewer lens changes occurring in this younger group. A larger study would lend more confidence to our findings.

If the modest gradient in risk with solar radiation in this study and the marked gradient seen in population studies is real, ultraviolet radiation may be the relevant part of the solar spectrum in the etiology of cataracts. This may be of particular importance for ocular health in light of recent reports of future amounts of ultraviolet radiation in our atmosphere from depletion of the ozone layer. Ultraviolet radiation has been used to create cataractous changes in animal lenses.[16] Both UV-A and UV-B are capable of producing lenticular damage.[17] Cataracts are produced experimentally using either a single high dose of ultraviolet radiation or multiple exposures to lower intensity. One may hypothesize that repeated insults of low intensity radiation over the course of a persons lifetime leads to cataracts. Damage may be done episodically, when sun exposure is of high intensity or long duration, with accumulations of aberrations ultimately leading to opacification. The slow progression of lens disease is consistent with this notion of accumulated damage in the lens.

Other risk factors for cataracts were found in our study. The apparent effect of tranquilizers was an unanticipated finding. Bartholomew and others[8] reported no association between the use of major tranquilizers and cataract. In our data, the tranquilizers used were probably sleeping pills or other barbiturates and minor tranquilizers such as diazepam, rather than "major tranquilizers". More detailed data on tranquilizers used should be included in future studies.

Our finding of increased risk among dark-eyed subjects is consistent with reports of high prevalence rates of cataracts in areas populated with dark-eye persons, e.g., India,[10] Nepal,[4] and Aborigines in Australia.[2] Black race was also reported as a significant risk factor for cataracts in the HANES data, but our study population had too few Blacks to study this factor.[5] While melanin protects against the carcinogenic effects of ultraviolet radiation to the skin, melanin in the iris may absorb solar radiation and provide higher amounts of exposure to the lens of the eye.[12] This finding needs replication in other population studies. Our study did not find factors such as eye injury[13] or diabetes[14,15] to be related to lens changes, although they have been

reported as risk factors in other studies. Smoking was evaluated for the first time and found not to be related to cataract risk. The positive associations between lens changes and eye color and tranquilizer use may stand up since a large number of comparisons were made and our numbers are small.

Other studies of lens disease are needed to confirm our findings and those of previously reported geographic studies. Residential history coupled with objective measurements of sun exposure, as attempted in this study, is necessary. Larger populations of cases and controls with substantial variation in sun exposure are also needed.

NCHS Report Analyzes Prevalence of Chronic Conditions in US

An analysis of the prevalence of selected chronic conditions in US citizens was recently published by the National Center for Health Statistics, using data from its annual National Health Interview Survey 1983-85.

The report ranks the top 10 chronic conditions for the total population, including breakdowns by age, sex, and race. It also shows the 15 most prevalent chronic conditions and the percentage of persons ever hospitalized due to them; chronic conditions were also ranked according to limitation of activity.

There was little difference between sexes in ranking of the top 10 chronic diseases; nine out of 10 chronic conditions ranked equally high.

- Sinusitis was the most prevalent chronic condition (31.2 million reported conditions annually); arthritis ranked second (30.3 million conditions); high blood pressure was third (28.6 million).
- Heart disease and diabetes were the chronic diseases most likely to require hospitalization (42.6 and 32.7 per cent, respectively).
- Chronic conditions causing highest limitation of activity were mental retardation (85.6 percent), followed by multiple sclerosis (76.8percent) and cancer of the lung and bronchus (68.2 per cent).
- Those under age 18 reported more respiratory conditions (hay fever, bronchitis, sinusitis and asthma) while the 65+ age group reported more cataracts, tinnitus, diabetes and hardening of the arteries.
- Among Blacks, high blood pressure was the most prevalent chronic condition reported (146.3 per 1000).

The top 10 chronic conditions in prevalence were very different from those with high levels of hospitalization and activity limitation. Less than 10 per cent of people with the three most prevalent conditions were hospitalized; sinusitis, the most prevalent chronic condition, caused limitations in less than .005 per cent of those reporting the condition.

Screening Prospective Blood Donors for AIDS Risk Factors: Will Sufficient Donors Be Found?

DAVID I. GREGORIO, PHD, MS, AND JEANNE V. LINDEN, MD, MPH

Abstract: Using data from various sources–we estimate that 14 to 19 per cent of American males 17–75 have personal histories that place them at high risk of transmitting the HIV infection while an additional 2 per cent of adult females may be similarly affected. Because roughly one fourth of either group may already be unsuited to give blood, we estimate that 10–14 per cent of adult males, and 1 per cent of females would be specifically deferred from giving blood because of personal histories of high-risk behavior. Local adjustments in the assumptions underlying these estimates are needed to apply them to given communities. (*Am J Public Health* 1988; 78:1468–1471.)

Introduction

Since 1983, blood collection centers in the United States have advised persons with AIDS (acquired immunodeficiency syndrome) or a history of behavior placing them at high risk of HIV (human immunodeficiency virus) infection to avoid donating blood.[1] Limited evidence suggests that voluntary self-deferral guidelines have produced the desired effect.[2–6]

Wykoff and Halsey[4] found that the blood donation rate by persons who were subsequently diagnosed with AIDS or Aids-Related Complex was reduced about 50 per cent following the implementation of self-deferral guidelines by blood collection centers in the New Orleans area. Kalish, *et al*,[5] similarly observed that the frequency of seropositivity detected among Connecticut blood donors fell approximately 75 per cent. Pindyck, *et al*,[6] reported that implementation of self-deferral guidelines by the Greater New York Blood Program (GNYBP) resulted in significantly fewer male donors appearing at blood collection sites, along with more potential donors being rejected because of personal histories of high-risk behavior uncovered through pre-donation health history screening, and a greater number of confidential requests from accepted donors that their blood not be used for transfusions.

Those results, along with our previous finding that a sizable number of adult Americans already may be unsuited to give blood,* prompted interest in estimating what proportion of our population that is otherwise eligible would be deferred as blood donors because of personal histories of high-risk behavior.

Methods

The overall proportion of eligible blood donors in the population is defined as adults, 17–75 years, who are not included within one or more of the American Red Cross/American Association of Blood Banks (ARC/AABB) donor deferral categories.[7] Of the many criteria currently used to screen prospective blood donors, the 16 most common reasons for deferring donations are summarized in the Appendix. As used in this exercise, they are specific to the American Red Cross Blood Services, Connecticut Region, although similar standards are used elsewhere.

Among the donor deferral guidelines cited, the first eight address matters of donor safety; the remainder pertain to the safety of blood products for use in transfusions. Of the latter eight criteria, three specifically address behaviors that increase a person's risk of HIV infection: histories of homosexual activity or prostitution as well as sexual encounters with prostitutes or other high-risk individuals.

For each of the 16 donor deferral categories summarized in the Appendix, established national data sources were used to estimate the proportions of our adult male and female populations possessing traits that would render them unsuited to give blood.[8–15] Whenever nationwide prevalence data were scarce, estimates were based on research findings by recognized experts.[16–28] As necessary, a range of prevalence estimates was considered to reflect "best" and "worst" case scenarios for estimating overall donor eligibility. All age- and sex-specific calculations were derived using the 1980 US population census.[29]

Since prospective donors could be unsuited for more than a single reason, the overlap among various traits was corrected according to the following rules: Whenever *a priori* associations among criteria could be assumed (e.g., intravenous (IV) drug use among female prostitutes), the unduplicated prevalence of either factor was estimated to equal the reported prevalence of the specific traits, minus the estimated overlap with other categories. When *a priori* associations could not be put forth (e.g., a history of heart disease among female prostitutes), we conservatively reasoned that since the probability of independent events occurring jointly is the product of their independent probabilities, such overlap would be proportional to the respective size of the specific deferral categories. Accordingly, the proportion of the population exhibiting one or more behaviors placing them at risk of transmitting HIV infections (and thus deferrable as blood donors) can be estimated as one minus the product of the

probabilities that persons are not included within one of the three AIDS risk factor deferral categories. Similarly, the unique proportion of the population deferred as blood donors because of AIDS risk factors, but otherwise suited to give blood (i.e., not already deferrable by criteria 1–13 of the Appendix table), is estimated to equal the proportion of AIDS risk factors among the population, multiplied by the proportion of other conditions that warrant deferral of blood donors.

Results

The estimated prevalence of traits that would require the deferral of blood donors are presented for both males and females in Table 1. Regarding criteria that pertain to blood donor safety (i.e., categories 1–8 of the Appendix), we estimate that 18 to 22 per cent of adult males and 39–41 per cent of women may be unsuited for giving blood. Among males, the greatest proportion of deferrals would be for reasons of a history of hypertension, having low hematocrit, or being over age. Women, on the other hand, would most likely be deferred for reasons of age, inadequate weight, or low hematocrit.

Between 20–25 per cent of adult men may be affected by conditions which threaten the safety of donated blood products. The prevalence of such traits among adult women, however, is not thought to exceed 8 per cent of that group's total population. The disparity stems from a greater prevalence of traits related to AIDS risk factors among males (i.e., categories 14–16 of the Appendix).

We conservatively estimate that 10–15 per cent of adult males would be unsuited as blood donors for reason of a homosexual experience since 1977. Sex partners of individuals who are at high risk of AIDS infections was estimated to affect 6 per cent of the adult male population and perhaps one-half of that amount among adult females. We further estimate that a history since 1977 of prostitution and/or a sexual encounter with prostitutes would affect considerably smaller proportions of the population.

Considerable overlap of AIDS risk factors among the population is known to exist. Therefore, the total portion of the population to be deferred as blood donors because of AIDS risk factors would be somewhat smaller than the simple sum of the estimated prevalences of particular AIDS risk factors among the population. For example, it is thought that one-half of all prostitutes, and those persons having had a sexual encounter with prostitutes, use IV drugs.[25] As many as one-third of male IV drug users are believed to have had histories of homosexual activity,[26] while a similar proportion of female drug users are believed to have engaged in prostitution.[27] Perhaps as many as one-half of women whose sex partners are from high-risk groups have themselves used IV drugs or engaged in prostitution, while one-fourth of males with sex partners from other high-risk groups have a history of IV drug use.[28] Taking these factors together, we estimate that 14–19 per cent of American males between the ages of 17 and 75, and roughly 2 per cent of adult females have personal histories that increase their risk of transmitting the HIV infection.

We calculated that donor deferral criteria unrelated to AIDS risk factors (i.e., criteria 1–13 of Table 1) could affect roughly one-fourth of adult males, and nearly one-half of females. Reducing estimates of the portions of the male and female populations with AIDS risk factors by such amounts to account for overlap among deferral categories suggests that 10–14 per cent of adult males, but perhaps as few as 1 per cent of females would be specifically deferred from giving blood because of a personal history of high-risk behavior. These amounts represent the unique reduction of our blood donor pool that might be attributed to ongoing efforts to screen individuals for AIDS risk factors.

Discussion

Of the roughly 165 million adults in this country 17–75 years of age, some 64 million persons (37 per cent) may not be suited to give blood for one of the various reasons cited in the above analysis. Of that number, we estimate that approximately 90 per cent would remain ineligible in the absence of AIDS risk factor screening. Individuals unsuited for giving blood specifically for reasons of being at greatest risk of transmitting HIV infections are thought to number between 8 and 11 million persons.

We caution, however, that data used here for national estimates may be unreliable and that the prevalence of specific traits will vary markedly from place to place.[30] Local adjustments in the assumptions underlying these estimates are needed to make them applicable to given communities.

Nevertheless, we are confident that the pool of suitable blood donors in this country may equal 100 million persons. Presently, only about 8 million adults (roughly 8 per cent of the eligible donor pool) donate blood during any year,[16] and surveys suggest that only one-half of Americans give blood during their lifetime.[18] Hence, there are many medically suitable persons who could be recruited as donors to supply blood products for the health care needs of this nation. Until the course of the HIV infection is better understood, persons at risk of transmitting HIV infections should not be permitted to donate blood. The adequacy of our nation's blood supply should not be adversely affected by such a practice.

While autologous transfusion is the simplest strategy to protect individuals from transfusion-related infections, a nationwide blood collection policy based solely on this approach is unwise. Most individuals in need of transfusion either suffer from unanticipated traumatic injuries or they do not qualify as blood donors because of ill health.

Expanded educational efforts to encourage self-deferral of high-risk individuals, in conjunction with donor recruitment efforts to retain former donors and effective laboratory testing of all blood products should be sufficient in assuring the safety of our nation's blood supply.

APPENDIX

Principal Criteria Used in Deferring Prospective Blood Donors

Deferral Category	Criteria for Deferral	Estimated Portion of US Population	
		% Males	% Females
Criteria Pertaining to Donor Safety (1–8)			
1. Age	Less than 17 or over 75 years of age unless permitted by physician to age 79)	5	9
2. Hematocrit	Less than 38% for women; 41% for men	5	23
3. Weight	Less than 110 pounds	<1	<1
4. Pregnancy	Less than 2 weeks post-abortion; 6 weeks post normal delivery; and 6 months post-cesarean section	0	3
5. Major Surgery	Less than 6 months post-operative	<1	<1
6. Heart Disease	Evidence of significant coronary artery disease (Coronary artery bypass graft, chest pain, arrhythmias, myocardial infarctions)	4	3

The San Francisco Men's Health Study: Continued Decline in HIV Seroconversion Rates among Homosexual/Bisexual Men

WARREN WINKELSTEIN, JR., MD, MPH, JAMES A. WILEY, PHD, NANCY S. PADIAN, MPH, PHD, MICHAEL SAMUEL, MPH, STEPHEN SHIBOSKI, MS, MICHAEL S. ASCHER, MD, AND JAY A. LEVY, MD

Abstract: The incidence of infection by the human immunodeficiency virus (HIV) has been monitored since 1984 in an area probability sample of homosexual/bisexual men drawn from a six-kilometer square area of San Francisco where the epidemic of acquired immunodeficiency syndrome (AIDS) has been most severe. Annualized HIV seroconversion rates in previously uninfected cohort members have declined by 88 per cent from 5.9 per cent during the first six months of 1985 to 0.7 per cent during the last six months of 1987. Concurrent declines of approximately 80 per cent in the prevalence of sexual behaviors associated with HIV transmission were also observed in the sample. (*Am J Public Health* 1988; 78: 1472–1474.)

Introduction

Declining sexual transmission of human immunodeficiency virus (HIV) infection among homosexual/bisexual men was first reported from the San Francisco Men's Health Study (SFMHS) in June 1987.[1] From an estimated annual HIV seroconversion rate of 18.4 per cent among seronegative study subjects between 1982 and 1984, the annualized infection rate dropped to 5.9 per cent (95% confidence intervals=2.8, 9.0) during the first six months of 1985 and to 4.2 per cent (95% CI=1.8, 9.3) during the first six months of 1986. These declines in HIV seroconversion rates were attributed to reductions of 60 per cent or more in the prevalence of HIV seronegative homosexual/bisexual men practicing insertive and receptive anal intercourse with multiple partners. Data are now available for HIV seroconversion rates and the prevalence of these high-risk sexual practices in this study population through 1987.

Methods

Sampling, data collection, laboratory, and statistical procedures for the SFMHS have been reported previously.[1,2] The cohort of 1,034 single men 25–54 years of age was obtained by stratified cluster sampling from a six kilometer square area of San Francisco where the AIDS epidemic has been most intense. Four hundred and eleven study subjects were HIV seronegative and homosexual/bisexual on entry into the study and have been examined at six-month intervals since the last half of 1984. The data for this report consist of HIV serostatus, determined by indirect immunofluorescent antibody assay for the first five examination cycles and by a standard enzyme-linked immunosorbent assay (DuPont) for the sixth and seventh cycles with confirmation of seroconversions by immunoblot, and numbers of sexual partners and frequency of anal intercourse determined by interview. The 95 per cent confidence intervals for annualized HIV seroconversion rates were obtained from published tables.[3]

Results

Time Trend of HIV Seroconversion

The data for HIV seroconversions in seven time periods for the SFMHS are shown in Table 1. Since the last report[1] for the period July–December 1986 when the annualized seroconversion rate was 4.2 per cent (95% CI=1.8, 9.3), the rate declined to 1.7 per cent (95% CI=0.3, 4.9) during the first six months of 1987 and to 0.7 per cent (95% CI=.002, 3.8) during the last six months of 1987. During the time the SFMHS cohort has been under observation, the annualized seroconversion rate has dropped by 88 per cent.

In order to evaluate the possibility that the declining HIV seroconversion rate was not due to selection bias, i.e., decreasing participation over time of men practicing high-risk behavior, participation in the SFMHS was evaluated according to risk status. Subjects who were HIV seronegative on entry were classified according to the number of male sexual partners, a major risk factor,[2] reported for the two years prior to the start of the SFMHS. Their rate of participation in subsequent examination cycles was then determined. The data, as shown in Table 2, indicate no relation between risk status on entry and subsequent participation. Furthermore, participation of HIV seronegative study subjects has remained quite constant since the second examination cycle, fluctuating around 80 per cent.

Changing Prevalence of High-Risk Sexual Practices

As already indicated, the sexual practices by which HIV is transmitted between homosexual/bisexual men are insertive anal intercourse by infected men, which disseminates infection, and receptive anal intercourse among uninfected men, by which they acquire infection. The prevalence of these practices with two or more male sexual partners during

*Numbers of male sex partners reported by HIV seronegative study subjects for two years before entering the SFMHS.

the six months before each examination cycle is shown in Fig. 1. Among HIV seropositive men, the prevalence of insertive anal intercourse with two or more partners in six months declined from about 40 per cent during January through June 1984 to about 15 per cent during the six months January through June 1985. The prevalence of this practice remained essentially unchanged during the succeeding 18 months, dropping to about 5 per cent during the first six months of 1987. The overall decrease in prevalence during the 36 months of follow-up amounted to about 87 per cent.

Among HIV seronegative men, the prevalence of receptive anal intercourse with two or more partners in six months declined from about 15 per cent during the six months January through June 1984 to about 5 per cent during the last six months of 1984. Prevalence of this practice has remained low since then, with the last reported prevalence for the period January through June 1987 at about 3 per cent. The overall decrease in the prevalence of this risk factor during the period of observation has been 80 per cent.

Discussion

Monitoring HIV seroconversion rates in representative samples of defined populations is an essential element in understanding the extent of epidemic spread of infection, evaluating the effectiveness of control efforts, and providing data for predicting the future extension of the epidemic, including incidence of the acquired immunodeficiency syndrome (AIDS) in the sampled population. This is the second report of HIV seroconversion rates from such a sample. The findings, however, will be of interest not only to those responsible for controlling the San Francisco epidemic, but also for other communities where sexual transmission of HIV infection among homosexual/bisexual men is a major problem.

The data reported here indicate that the previously reported decline in the spread of infection, from an estimated annual rate of approximately 18 per cent per year between 1982 and 1984 to approximately 4 per cent per year during the first six months of 1986,[1] has continued. For the latest period of observation, July through December 1987, the annualized HIV seroconversion rate in the SFMHS cohort was 0.7 per

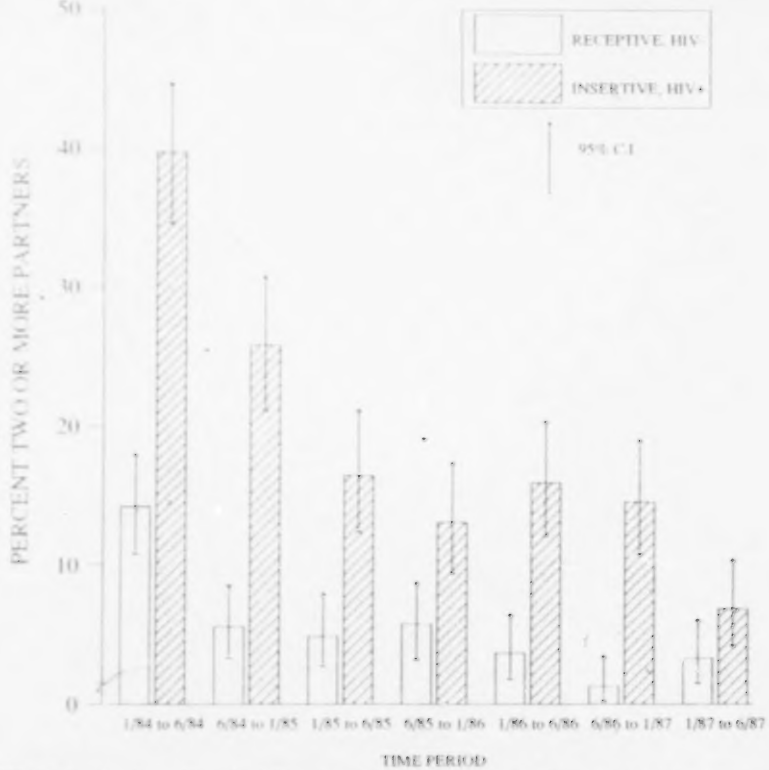

FIGURE 1—Prevalence of Sexual Behaviors Associated with Acquisition and Dissemination of HIV Infection among Homosexual Bisexual Men, SFMHS, January 1984–December 1987

cent. This low rate of infection was unlikely to be attributable to selection bias of study participants. A more likely explanation is the decline in the prevalence of the major modes of transmission, insertive anal intercourse among HIV seropositive homosexual/bisexual men, and receptive anal intercourse among HIV seronegative homosexual/bisexual men.[1] The decline in HIV infection rates in San Francisco has also been demonstrated in a cohort of homosexual/bisexual men originally recruited from sexually transmitted disease clinics for studies of hepatitis B infection and followed from 1978 to the present.[4]

ACKNOWLEDGMENTS

Indirect immunofluorescent antibody determinations of HIV antibody status were carried out in the Laboratory of Dr. Jay A. Levy, Cancer Research Institute, University of California at San Francisco. Enzyme linked immunosorbent assays and immunoblot confirmation of HIV seroconversions were carried out in the Viral and Rickettsial Disease Laboratory of the California Department of Health Services under the direction of Dr. Richard W. Emmons. This research was supported by contract NO1-AI-32519 from the National Institute of Allergy and Infectious Diseases. An earlier version of this paper was presented in part at the International Congress for Infectious Diseases, Rio de Janiero, April 17–21, 1988.

Next-of-Kin Attitudes Regarding Participation in an Epidemiologic Case-Control Study

LINDA HEUSER, MA, RICHARD K. SEVERSON, PHD, AND TERESA J. WATSON

Abstract: We assessed next-of-kin's attitudes about participating in an epidemiologic case-control study of adult acute nonlymphocytic leukemia. Responses from a mailed questionnaire indicated that 95 per cent were glad they participated. While 74 per cent benefited, 18.5 per cent were bothered in some way. Results concerning the need to obtain physician permission before contacting next-of-kin were inconclusive; however, 8 of 10 females contacted by the case's physician considered consent necessary. (*Am J Public Health* 1988; 78:1474–1476.)

Introduction

Case-control studies have become an increasingly popular method in epidemiologic research. Depending upon the disease under study, some eligible cases may die before a personal interview can be conducted. In those instances, investigators may choose to ask the next-of-kin to provide information that would otherwise be obtained directly from the case.

While living subjects have been asked about their attitudes toward participating in epidemiologic case-control studies,[1,2] little empirical data is available to evaluate the opinions of interviewed next-of-kin. The present survey examines next-of-kin's attitudes about their participation in a population-based case-control study of adult acute nonlymphocytic leukemia (ANLL).

Methods

The present survey was conducted as the final phase in an investigation of ANLL and residential exposures to power-frequency magnetic fields in King, Pierce, and Snohomish counties of Western Washington State. Eligible cases were identified through a population-based SEER (Surveillance, Epidemiology, and End Results) registry and included 164 individuals aged 20 through 79 who were diagnosed with ANLL from 1981 through 1984. Personal interviews took place between November 1984 and February 1986. Of the 139 cases who had died prior to being contacted by study investigators, interviews were successfully completed with 94 (67.6 per cent) of their next-of-kin (Table 1).

Each respondent could be asked to participate in two different parts of the study. First, a one hour personal interview was conducted in the next-of-kin's home. If the case had lived at this residence one or more years before her/his diagnosis date, the interviewer also took magnetic field measurements in the kitchen, bedroom, and family gathering room. Second, scientific instruments were installed in a limited sample of homes for the purpose of measuring magnetic fields over a 24-hour period of time.

TABLE 1—Next-of-Kin Response Rates for Original Interview and Mailed Questionnaire

Outcome	Original Interview		Mailed Questionnaire	
	No.	(%)	No.	(%)
Identified as eligible	139	(100.0)	94	(100.0)
Physician refusal	29	(20.9)	NA	
Next-of-kin refusal	8	(5.8)	12	(12.8)
Moved/unable to locate	6	(4.3)	0	(0.0)
Other reason	2	(1.4)	1	(1.1)
Total completed interviews/ questionnaires	94	(67.6)	81	(86.2)

NA, not applicable

One month after the completion of the personal interview, a two-page self-administered questionnaire was mailed to each next-of-kin in which they were asked to assess their feelings about participating in the study. Simple descriptive statistics have been used to present the results of that survey.

Results

Of the 94 next-of-kin interviewed in the original study, 81 (48 spouses and 33 other relatives) completed the mailed questionnaire (Table 1). Seventy-seven (95 per cent) of the respondents indicated that they were glad to have participated in the study. In answering the question about why they agreed to be interviewed, the vast majority expressed the hope that their participation might help others who have cancer (Table 2).

A high percentage of the next-of-kin said they benefited from their participation compared to a small percentage who were bothered (Table 2). Of those who benefited from their participation, 15.0 per cent were nonetheless bothered by some aspect of the study. In contrast, 33 per cent who received no benefits indicated that they were bothered.

When next-of-kin were asked whether they felt it was necessary for the investigators to obtain consent from the case's physician prior to contacting them, a slightly higher proportion thought physician permission was not necessary (35 versus 28, with 18 professing not to know). The attitudes of next-of-kin, presented in Table 2, varied little by sex, relationship to the case, combined family income, number of years the next-of-kin knew the case, number of months between death and the interview, or interview type (with or without magnetic field measurements). However, females, spouses, and respondents whose interviews included magnetic field measurements were more likely to feel that physician permission was necessary.

Sex also seemed to influence who the physician told about the study; the 10 next-of-kin contacted by the case's physician were all female (nine spouses and one daughter). While eight of these 10 females felt that physician consent was necessary, only five of 25 males and 15 of 44 females who were not contacted by a physician agreed.

TABLE 2—Perceived Feelings about Participation in Study

	No.	(%)
Why participated in study		
It might help other people who have cancer	75	(92.6)
I might be able to get some information	23	(28.4)
It might be interesting	19	(23.5)
I might find comfort in discussing my feelings with someone	12	(14.8)
My family or friends thought it was a good idea	7	(8.6)
Other reasons participated	8	(9.9)
Reasons benefited		
No benefits	15	(18.5)
Unknown benefits	6	(7.4)
Possible improvement in future medical care for others	48	(59.3)
Satisfaction of helping others	40	(49.4)
Educational experience	17	(21.0)
Interesting experience	14	(17.3)
Comfort in discussing my feelings with someone	10	(12.3)
Other benefits	2	(2.5)
Reasons bothered		
Not bothered	64	(79.0)
Unknown if bothered	2	(2.5)
I had inadequate information to answer the questions	5	(6.2)
Some questions were tedious or boring	3	(3.7)
It brought back painful, depressing memories	3	(3.7)
Some questions were too personal	2	(2.5)
There were no questions about leukemia	2	(2.5)
The interview took too long	1	(1.2)
Other reasons bothered	4	(4.9)

Discussion

The results from this study demonstrate that very few next-of-kin were upset by their participation. In fact, the vast majority benefited from their involvement and were glad to have been contacted. This corroborates the reports concerning the opinions of living cases and controls,[1–4] and extends those results to the experience of next-of-kin as research participants.

Results regarding the need to obtain physician consent are inconclusive. In most epidemiologic studies, the next-of-kin are not approached until some months after the case's death. Since the physician may not see the next-of-kin after the case dies, she/he may not be able to make an informed decision concerning the advisability of next-of-kin participation in a research study. Institutional review board policy that requires physician consent to contact next-of-kin may lead to what Lebacqz and Levine[5] and Rothman[6] describe as overprotection of the individual and abrogation of her/his privilege to contribute to expanding medical knowledge.

Boring, *et al*, reported that female cases whose doctors had contacted them were more likely to believe that physician consent was necessary;[2] the present study found similar results for female next-of-kin. Moreover, spouses and respondents whose interviews included magnetic field measurements were also more likely to feel physician permission was necessary. The nature of the next-of-kin's relationship to the deceased case and the type of interview may influence how the respondent feels about her/his participation.

These data should be interpreted with caution. First, only 58.3 per cent of the original next-of-kin pool responded to the mailed questionnaire. In addition to a limited sample size, it is possible that respondents with negative attitudes were excluded by the case's physician or their own refusal to participate. Second, the next-of-kin's feelings may vary based on the clinical course of the disease. This study relates to ANLL only. Additional studies may be useful in evaluating the effects of various diseases on the next-of-kin's feelings. Pre- and post-interview attitude surveys might also be of interest. Such information could provide valuable insights for institutional review boards as they assess the potential impact of proposed research on study participants.

Inadequate Utilization of Routine Electronic RBC Counts to Identify Beta Thalassemia Carriers

ODED SHALEV, MD, EDNA YEHEZKEL, BMEDSC, AND ELIEZER A. RACHMILEWITZ, MD

Abstract: We investigated physician awareness of the diagnosis of beta thalassemia minor as suggested by RBC indices obtained from routine electronic counts; and, the knowledge of the carriers of their genetic trait. Out of 17,000 counts, 324 were compatible with the diagnosis of beta thalassemia minor, but, only 175 (54 per cent) were identified by physicians as possibly thalassemic and in 47 of these (27 per cent) was the diagnosis verified. Twenty-four of 39 interviewed patients in whom the diagnosis of beta thalassemia minor was established knew about their carrier state. (*Am J Public Health* 1988; 78:1476–1477.)

Introduction

Thalassemia is the most prevalent hereditary hemoglobinopathy afflicting millions of individuals worldwide. It is a genetic disorder affecting synthesis of the globin moiety of the hemoglobin (Hb) molecule. The beta thalassemias are prevalent in a broad belt extending from the Mediterranean basin to Southeast Asia. In Israel it is the most common hemoglobinopathy with an absolute gene frequency of 0.1.[1] Beta thalassemia major denotes the homozygous, severe, transfusion dependent form of the disease (Cooley's anemia) of which 100,000 children die annually worldwide.[2] Beta thalassemia minor, on the other hand, is associated with mild or absent anemia but with reduced mean corpuscular volume (MCV) and mean corpuscular hemoglobin (MCH) and elevated HbA_2. The majority of thalassemia minor individuals, who are heterozygous for the beta thalassemia gene, are asymptomatic and unless diagnosed and informed may be unaware of their carrier state.

A basic tenet in the overall management of the beta thalassemia, as for any autosomal recessive disorder, is the prevention of its homozygous form through the detection and education of the heterozygous carriers. One way of achieving this goal is to screen populations at risk and instruct the identified heterozygous carriers about the genetic implications of marrying another carrier.[3] Of all screening tests so far advocated for beta thalassemia minor, electronic counts of red blood cells (RBC) indices is the best.[4–7] Electronic RBC counts is a rapid, automated, inexpensive and widely used test. The most striking and consistent finding in heterozygous beta thalassemia is the combination of a relatively high RBC count with a low MCV and MCH along with normal Hb and hematocrit values.[8–13] In fact, the MCV alone is a sensitive parameter, identifying a high number of thalassemia carriers both in adults and children (99.3 and 98.1 per cent, respectively).[14] In an adult Mediterranean population, the percentage of false negatives was as low as 0.7 per cent.[14] Since electronic cell counts are now obtained routinely worldwide, entire populations are screened de facto for thalassemia at no additional cost to the medical system. The present study was designed to assess the awareness of physicians to the possible diagnosis of beta thalassemia minor in adults as suggested by typical RBC indices, and the knowledge of diagnosed carriers about their status and its significance.

Methods

Medical records of the first 17,000 adults whose charts contained complete electronic blood counts were reviewed: 12,920 counts of patients hospitalized in Hadassah University Hospital, Jerusalem, and 4,080 gathered from associated community clinics. The counts were examined for compatibility with the diagnosis of thalassemia trait; criteria for compatibility were an RBC count of more than $6 \times 10^6/mm^3$ ($6 \times 10^{12}/L$), MCV less than 72 femtoliter and MCH less than 25 picogram, with normal Hb and Hct values. When RBC indices compatible with the diagnosis of thalassemia minor were found, the charts were searched for any note relating to this abnormality. When no mention was noted, the abnormal results were deemed ignored. When they were noted and thalassemia minor suspected, we looked for verification of the diagnosis: demonstration of elevated HbA_2 and/or HbF concomitant with normal or high serum iron.

Patients in whom the diagnosis of beta thalassemia minor was established were interviewed individually in order to determine their knowledge of the disease. The standardized interview included questions regarding awareness of the trait, its genetic implications, prenatal diagnosis, and symptomatology of the homozygous form.

Results

In 324 of the 17,000 (1.9 per cent) records reviewed, the electronic RBCs were compatible with the diagnosis of beta thalassemia minor. However, in only 54 per cent (175/324) was any mention of the abnormality noted in the chart even though all 324 individuals belonged to ethnic groups at risk for beta thalassemia (Iraqi or Kurdish extraction). The proportion of recognized abnormal indices was higher (62 per cent) in records of hospitalized patients compared with that of community-based charts (38 per cent).

valid *legal* reasons for physician-initiated blood alcohol concentrations. When blood alcohol concentrations are used to provide realistic individualized patient guidelines regarding drunken driving, legal issues become moot: the patient's health becomes the only motivating factor, and the use of blood alcohol concentrations becomes equivalent to any other laboratory test obtained for diagnosis and treatment.

It is possible, given a blood concentration, to predict on average how long it will take for the level to decrease to a specified level.* This information can be used to provide impaired patients with a written "driving prescription" indicating the minimum time during which driving should be avoided. Since patients will vary in their metabolism of alcohol, the "driving prescription" should be conservatively based on time to a blood alcohol level of zero. The written prescription serves several useful purposes: it encourages physicians to provide realistic advice tailored to the individual patient; serves as a reminder for the sobering patient should they forget verbal instructions; should be medically acceptable; and demonstrates physician concern with the health consequences of driving while impaired.

Any diagnostic test should be obtained only for medical reasons that might lead to some benefit for the patient. This implies that action will be taken once the results of the test are known. More liberal use of blood alcohol concentrations might lead to advice for impaired patients, who are not obviously intoxicated, to refrain from driving. Such advice, if translated to fewer traffic crashes, would improve patient care. Since driving while impaired creates tremendous health risks, an explicit "driving prescription" may be an important medical intervention that could also promote highway safety.

*The average time to a specified alcohol level, along with other relevant parameters regarding alcohol drinking, can be predicted using the "Alco-Calculator (Alcohol Research Documentation, Inc., Rutgers University Center of Alcohol Studies, New Brunswick, NJ). The calculation assumes drinking has stopped sometime prior to the obtained blood alcohol concentration and is an estimation based on the population average.[10]

Prescribing of Noncontraceptive Estrogens and Progestins in the United States, 1974–86

ELINA HEMMINKI, MD, DIANNE L. KENNEDY, RPH, MPH, CARLENE BAUM, PHD, AND SONJA M. MCKINLAY, PHD

Abstract: This paper describes changes in the prescribing of noncontraceptive estrogens and progestins, using data from pharmaceutical marketing surveys. The number of estrogen prescriptions decreased from 1975 to 1980, and then increased through 1986. Progestin use has increased since 1982; concomitant use of estrogens and progestins increased over time and was common in 1986. The trends suggest that the use of estrogens, particularly the combined use of estrogens and progestins, will continue to increase. (*Am J Public Health* 1988; 78:1478–1481.)

Introduction

Both positive and negative health effects of estrogen use have been reported.[1–5] Nevertheless, it is important to be aware of changes over time in the use of estrogens and of the characteristics of women exposed in order to estimate the public health importance of any effects. The notable changes in the quantity of prescribing of noncontraceptive estrogens in the United States from 1966 to 1983 has recently been described.[6] This paper describes the changes in the patterns of and indications for prescribing of noncontraceptive estrogens from 1974 to 1986.

Methods

Data were derived from two pharmaceutical marketing research data bases purchased by the Food and Drug Administration (FDA) from IMS America, Ltd, Ambler, PA: the National Prescription Audit (NPA) and the National Disease and Therapeutic Index (NDTI).[6,7] The NPA gives national estimates of prescription volume based on prescriptions dispensed by a panel of retail pharmacies. The NPA data presented are for all dosage forms of estrogen and include estrogen/androgen combination products.

The NDTI provides descriptive information on disease patterns and treatment in office-based practice in the US. A

panel of over 2,000 physicians report on each patient seen or contacted (patient *visit*) in any way (office, hospital, telephone) during a 48-hour period each quarter. There are no published reports on the quality of the NDTI data, but we have assumed the possible biases to be similar over time, and the data valid for secular comparisons. Drugs reported during a patient visit ("mentions") may have been given as a formal prescription, hospital order, directly dispensed or administered, or just recommended. Concomitant use of drugs means drugs prescribed for the same diagnosis, and does not include drugs ordered for the same patient for different diagnoses. When regional variation was studied, the total number of drug mentions regardless of age was divided by the estimated number of women aged 45–64 years in the region.[8,9,10]

Results

The previously reported increase in estrogen prescription volume from 1980 to 1983 has continued through 1986, (Figure 1). In 1983, 16.6 million prescriptions for estrogen-containing products were dispensed, and in 1986 20.3 million: 37 per cent new and 63 per cent refills. Oral estrogens accounted for 88 per cent of estrogen prescriptions in 1986, with Premarin® still the most commonly used preparation. Vaginal estrogen products show little variation over time (2 million in 1986), and androgen/estrogen preparations are down from 7 per cent in 1974 to 1 per cent in 1986.

According to the NDTI data, the use of injectable estrogen has decreased from 5.0 million doses in 1974 to 1.8 million doses in 1986 while the use of oral estrogens increased 117 per cent between 1979 and 1986. Because each injection requires a patient visit, they get disproportionately more emphasis in the NDTI than oral estrogens. To minimize confounding that might be caused by the decreased use of injectable estrogens over time, further NDTI data on time trends will mainly concern oral estrogens.

The rate of prescribing of oral estrogens varied notably by region in the US, being lowest in the East and highest in the West (Table 1). Differences between the areas increased from 1974 to 1985, but the rankings remained the same. Similar differences were found for all estrogens. The share of oral estrogens prescribed by gynecologists rose while that prescribed by general/family practitioners declined from 1974 through 1986.

Oral estrogens were used mainly in women (92 per cent in 1986), aged 40–59 years (Table 2). In different years from

66 to 82 per cent of oral estrogens were prescribed for problems associated with menopause or post-menopausal changes. The other important indication was cancer.

Other drugs have been frequently prescribed along with an estrogen (Table 3). Concomitant use of progestins increased substantially during the 1980s.

The NPA shows that the total number of progestin (P) prescriptions rapidly increased between 1984 and 1986 (Figure 1). In 1979, oral progestins were given mainly to women under age 40 (71 per cent of use), they were used alone (79 per cent), and for first-time therapy (81 per cent); menopausal problems represented only 18 per cent of the diagnoses. In 1986, oral progestins were given to women 40 years and older (68 per cent), only 37 per cent were used alone, 52 per cent were new therapy, and menopausal indications represented 59 per cent of diagnoses.

"Menopausal symptoms" was the most common diagnosis for which estrogens were prescribed (from 32 to 46 per cent of all estrogen use each year), as shown in Table 4. A drug was prescribed in most of the visits for "menopausal symptoms", and the use of oral estrogens and progestins in the treatment of "menopausal symptoms" has increased.

The number of visits with the diagnosis "osteoporosis" was 1.4 million in 1974 and 1.8 in 1986. The majority of visits (from 86 to 96 per cent) were made by women, and in 1974–82 most of them were age 60 or older. Since 1982, the proportion of visits by women ages 40–59 years have increased (up 17 per cent in 1986). The importance of non-combination estrogens in therapy increased from 1974 to 1986, and in 1986 over one-fourth of the patients received oral estrogens. However, calcium supplements were the most commonly prescribed therapy throughout the 1980s.

Discussion

The increase in estrogen prescriptions which began in 1980 continued through 1986, but the highest level was still

somewhat lower than in the peak year of 1975. The increase in the prescribing of progestins started somewhat later (after 1982) and coincided with a trend toward the use of an oral progestin along with an oral estrogen. Injectable forms of estrogens and estrogen/androgen combinations have lost their popularity with time. These changes may be due to changes in prescribing habits or in the specialty of prescribing physicians.

As the overall prescribing went down, prescriptions for menopausal symptoms were most affected, prescriptions for surgical menopause and cancer less affected. This is also reflected in the sex and age distribution of patients receiving estrogens.

When the number of NDTI drug mentions for estrogens dropped by 59 per cent from 1974 to 1979, there was only a small drop (16 per cent) in the proportion of women with "menopausal symptoms" who were treated with oral estrogens. In contrast there was a large drop (64 per cent) in the number of visits in which this diagnosis was given. There are two possible explanations for this finding: it may be that treatment determined recording of diagnosis, and visits not having any prescriptions were underreported in the NDTI data base; or that women changed their help-seeking behavior, and the changes in the number of visits were real.

Osteoporosis as a distinctive diagnosis in estrogen therapy was rare although it became somewhat more common over time. However, the classification of reasons for visits in NDTI emphasizing the underlying problem rather than the aim of the treatment may underestimate the prevention of osteoporosis as a reason for estrogen therapy.

Consistent with earlier studies,[11,12] this survey showed that if a woman consults a doctor because of menopausal problems, she is very likely to get a prescription for estrogens. Given the purported benefits of estrogens and combined estrogen-progestin treatment, including claims that they are protective against cardiovascular diseases, and current concerns about osteoporosis, it appears that increased prescribing of estrogens will continue for some time.

Decreased Incidence of Hip Fracture in Hispanics, Asians, and Blacks: California Hospital Discharge Data

STUART L. SILVERMAN, MD, AND ROBERTA E. MADISON, DRPH

Abstract: We examined the incidence of hip fracture in Non-Hispanic White, Hispanic, Black, and Asian Americans for the years 1983 and 1984 using a data base which contains a summary of all hospitalizations for the state of California. We found a consistently lower risk for hip fracture after age 60 in Hispanic, Black, and Asian American females than in White females who were not Hispanic. Overall age-adjusted hip fracture rates in Hispanic, Black, and Asian females were 49.7, 57.3, and 85.4, respectively, and 140.7/100,000 in White females who were not Hispanic. These differences were not found in males, although Whites (not Hispanic) had the highest incidence of hip fractures among males. (*Am J Public Health* 1988; 78:1482–1483.)

Introduction

Hip fracture, a major outcome of osteoporosis, is a significant cause of disability and mortality in the United States.[1]

There is relatively little published data on the incidence of hip fractures in ethnic groups. Previous epidemiologic studies have shown White females to have a twofold increased risk for hip fracture as compared to Black females[2] or Mexican Americans.[3]

Using a statewide hospital discharge data base for the State of California in the years 1983 and 1984, we estimate the incidence of hip fractures in four ethnic groups: Hispanics, Blacks, Asian Americans, and Whites who are not Hispanic.

Methods

The California Discharge Data Program under the administration of the California Health Facilities Commission maintains records of all hospital inpatient discharges from acute care hospitals in the State.[4] The data base was complete for the years 1983 and 1984. Race was categorized as White, Black, Hispanic, native American/Eskimo, Asian, other, and unknown. There were 3,551,874 hospitalizations in 1983 and 3,538,094 in 1984. Hip fractures were identified by the principal diagnosis of either capsular or intertrochanteric fracture, ICDA-9 codes 820.0 to 820.9.[5]

Age-specific and age-adjusted hip fracture incidence rates were calculated specific for sex and ethnicity for 1983 and 1984, and then averaged. The 1983 and 1984 population in each ethnic group was estimated from data derived from the US Census for 1980[6] and the Center for Continuing Study of the California Economy for 1985.[7] Age-adjusted incidence rates were calculated using the total 1980 California population as the standard, with the 10-year intervals of age.

Results

In 1983, there were 17,556 hospital discharges for hip fractures in females, of which 16,898 occurred in White (not Hispanic), Hispanic, Black, and Asian females (143 were classified as American/Indian/other, and 515 as race unknown). Comparable figures in 1984 were 15,626 and 15,289 (134 American Indian/other, and 203 race unknown).

Age-adjusted and age-specific incidence rates of hip fracture within each ethnic group are shown in Table 1. White (not Hispanic) females had the highest age-adjusted rate at 140.7, while Hispanics, Blacks, and Asians were lower, at 49.7, 57.3, and 85.4, respectively. The incidence rate of hip fracture increased exponentially with age in all four ethnic groups.

In 1983, there were 5,914 hospital discharges for hip fractures in males. Of these, 5,729 occurred in White (not Hispanic), Hispanic, Black, and Asian males (40 were classified as American Indian/other, and 145 as race unknown). Comparable figures in 1984 were 5,292 and 5,185 (49 classified as American Indian/other, and 58 as race unknown).

Male hip fracture incidence rates within each ethnic group are shown in Table 2. White males (not Hispanic), like their female counterparts, have the highest age-adjusted incidence rates at 48.9/100,000, while Hispanics, Blacks, and Asians are lower at 22.2, 38.7, and 26.3, respectively. The rate of increase in incidence of hip fracture in males is initially less than that of females but beginning in the sixth decade there is a discontinuity with a rapid exponential increase thereafter. The hip fracture rate of Black males is similar to White males until the seventh decade. The hip fracture rate of Hispanic and Asian males remains consistently lower than White males in all decades.

The age-specific incidence rates for men are greater than those for women in the first five decades of life, with female-to-male ratios of 0.42 to 0.54. After age 60, the relationship reverses in all groups except Blacks, with female-to-male ratios varying from 11.7 to 2.3. By age 70, sex ratios are higher for females in all ethnic groups, ranging from 1.4 to 2.2. By the oldest ages, the incidence rate for men has increased sharply but still trails the incidence rate for women, with female-to-male ratios of 1.2 to 2.6.

Sex ratios based on age-adjusted overall rates of hip

TOTAL	48.9	22.2	38.7	26.3

fracture were highest in Non-Hispanic Whites and Asians (2.9 and 3.3, respectively) and lower in Hispanics and Blacks (2.2 and 1.5, respectively).

Discussion

Our estimated incidence rates were subject to errors of ascertainment of the number of cases (the numerator) as well as the total susceptible population (the denominator). The number of cases may have been under- or overestimated by misclassification of disease or ethnicity. Although general validity studies have been done by the State of California, the investigators were unable to validate the specific ICDA codes used in this study due to the confidential nature of the data base.

Significant errors in ascertainment of ethnicity of individual cases may occur. In 1983, 3 per cent of hip fracture cases had unknown ethnicity (1.3 per cent in 1984).[4]

The number of cases would be underestimated if patients were treated outside of a hospital, but such events are rare since hip fracture usually necessitates hospitalization.

The number of cases may have been overestimated due to readmissions or admissions due to a second fracture in the same year. Readmission is possible but the ICDA code for principal diagnosis should specify a complication of the fracture or operative intervention. Previous studies have found the incidence rate of second hip fracture to be 9 per cent in a 10-year period.[8] This suggests that refracture would increase the incidence rate at less than 1 per cent per year in patients with prior fracture.

Some errors in the estimation of the total susceptible populations probably occurred. In this study, the likely effect of underestimation of the denominators would be to decrease differences between Whites and other ethnic groups. Thus, our estimates of ethnic differences may be underestimated.

Risk factors for hip fracture include dietary intake,[9] reproductive history,[9] anthropometric data,[9] and bone-mineral content.[9,10] We observed striking differences between ethnic groups in their incidence rates of hip fracture. However, some of these known risk factors cannot easily explain these ethnic differences. Hispanics have a lower dietary intake of calcium than Whites[11] but a lower rate of hip fracture. Asians have lower bone mineral content than Whites,[12] yet Asians in our study had a decreased risk. The time of menopause is similar in all ethnic groups.[13]

We conclude that both male and female Hispanics, Blacks, and Asians have lower risks of hip fracture than do Whites who are not Hispanic. Further studies are needed to define differences in risk factors between these ethnic groups. Information concerning differences in hip fracture rate and risk factors may be helpful in designing prevention strategies for different ethnic groups.

The Stability of Health Status in Rheumatoid Arthritis: A Five-Year Study of Patients with Established Disease

ROBERT F. MEENAN, MD, MPH, LEWIS E. KAZIS, ScD, AND JENNIFER J. ANDERSON, PhD

Abstract: We employed a health status measure to describe the outcomes of rheumatoid arthritis patients over five years. Of the 410 rheumatoid arthritis patients who were originally administered the Arthritis Impact Measurement Scales (AIMS), 299 completed a follow-up five years later. Data were analyzed using nine health status scales, three components of health status, and an overall arthritis impact item. Results for survivors indicated that there were no clinically important deteriorations in any of these measures. In fact, small improvements on most measures were found. The health status changes were similar for patients originally in a clinical trial and for those receiving routine specialty care. Age was found to positively relate to improvements in psychological status and overall arthritis impact, but we were unable to demonstrate any consistent effects of sex, marital status, education, or disease duration. Our results contrast with other studies that have noted major declines over time in the health status of patients with rheumatoid arthritis. Furthermore, level of education was not a major determinant of morbidity in this group. These results suggest that health status in certain patients with rheumatoid arthritis is more stable than previously thought. This has implications for both clinical practice and clinical research in rheumatology. (*Am J Public Health* 1988; 78: 1484–1487.)

Introduction

Rheumatoid arthritis (RA) is a chronic disease that generally leads to structural damage and functional disability. In the past, the course of rheumatoid arthritis was monitored in practice and described in the literature most often in terms of standard clinical variables such as joint count, range of motion, and x-ray erosions. Studies using these measures generally painted a picture of steady and severe decline over time.[1,2] More recently, functional status measures have been employed to study the impact of rheumatoid arthritis. In general, such studies also have suggested that functional loss over time is substantial.[3,4] Age, sex, duration of illness, and level of education have been shown to be predictors of disability in these studies.

This study used the Arthritis Impact Measurement Scales (AIMS) to describe health status changes over five years in a group of subjects with established rheumatoid arthritis. The AIMS is a reliable and valid assessment tool that has previously been shown to be sensitive to changes in health status in RA.[5,6] Our results indicate that health status in rheumatoid arthritis may be quite stable over time. We also found that sex, age, marital status, education, and disease duration were relatively weak predictors of changes in health status.

Methods

The AIMS is a patient self-administered questionnaire that includes 64 items of which 45 are specific health status questions.[7] These items are grouped into nine scales which address the following aspects of health status: *mobility* (ability to move around the community); *physical activity* (lower extremity functions); *dexterity* (upper extremity functions); *household activities* (basic household tasks); *activities of daily living* (basic self care activities); *social activity* (social interactions with friends and family); *anxiety*; *depression*; and *pain*.

Previous work has demonstrated that these nine scales can be summarized into three broad components of health status: *physical disability* (which includes mobility, physical activity, dexterity, household activities, and activities of daily living), *psychological status* (which includes depression and anxiety), and *pain*.[8] The AIMS instrument also contains a single visual analogue scale that assesses overall arthritis impact. This item measures the patient's overall assessment of the effect of arthritis on their health status. All of the AIMS scores are rescored to a 0 to 10 range where lower scores represent better health status.

The AIMS questionnaire was originally administered to 410 patients with classical or definite rheumatoid arthritis between 1978 and 1982. Patients were gathered from a variety of rheumatology practice settings in 10 different states. Two different patient populations were involved: 51 per cent were from clinical settings where they were receiving routine specialty care while 49 per cent were initially involved in a 21-week cooperative drug trial which compared placebo, oral gold, and injectable gold.[9] Since the study was not designed to assess the effect of treatment, there were no restrictions on therapy and no data were collected on which drugs patients had taken.

A second AIMS administration was conducted by mail from 1983 to 1986 such that there was approximately a five-year lag between the first and last administrations for all respondents. Rigorous follow-up procedures were used to improve response rates including the tracking of lost patients through friends, relatives and neighbors by the last known residence recorded for a patient. We also examined death records by locality for patients who did not respond to the mailings. Patients not responding to any of three mailings and not located in the death registry was considered lost to follow-up. Of the 410 rheumatoid arthritis patients who were initially administered the AIMS instrument 299 patients completed a follow-up questionnaire five years later. This represented 73 per cent of the group. Among the non-respondents, 37 (9 per cent) were known to be deceased and 74 (18 per cent) were lost to follow-up either because they had refused to participate (4 per cent) or had not responded to any of the mailings (14 per cent).

Analysis of the data began with an examination of the baseline comparability between the patients in the completed study group, those who were lost to follow-up, and those who died. We also compared the baseline scores of those who were initially in the clinical trial with those who were not. These comparisons included the demographic variables, the

three health status components, and the overall arthritis impact score. The differences between the patient's AIMS scores on the two administrations were calculated, with a minus indicating more disability or worsening on a particular scale or component and a plus indicating improvement. Changes in the AIMS scores had a potential range of minus 10 to plus 10. The mean change and 95 per cent confidence intervals for each of these health status scores were estimated.

Preliminary bivariate associations between change scores and selected disease and demographic characteristics were obtained. Those variables with a significant association at the .05 level were included as explanatory variables in a multivariate regression analysis of the changes in health status scores. Next, the multivariate analysis was adjusted for initial baseline measures of physical status, psychological status, and pain. A final adjustment in the multivariate analysis was the inclusion of a dummy variable to distinguish the general and clinic study populations.

Results

The average age of the 299 patients who completed the follow-up was 52; they were predominantly female (69 per cent), and White (83.5 per cent); 36.9 per cent of the group had more than a high school education and 14.5 per cent were in professional occupations. The average disease duration in the group at the second administration was 14 years. Patients who completed the questionnaire were significantly more likely to be White, married, better educated, and have a higher income than those who died or were lost to follow-up. The baseline health status of the three groups was comparable, with the exception of the physical function of the deceased group which was worse. The routine care and clinical trial subgroups were similar for sex, marital status, education, occupation, income, and disease duration. However, the routine care group was older and more often White.

Baseline health status scores and change scores at five years for those who completed the second AIMS questionnaire are shown in Table 1. Baseline scores ranged from 6.30 for physical activity to 0.95 for ADL. The overall arthritis impact score at baseline was 4.36. No substantial deterioration was found at five years in any of the health status measures. In fact, almost all of the scales and components showed a trend toward slight improvement. Health status change scores were comparable for the clinical trial and routine care segments of the sample when adjusted for their initial baseline values.

A series of multivariate regression analyses were performed to examine the effect of selected study variables on changes in the health status components and arthritis impact scores. Four separate regression equations were constructed, one for each of the health status components and one for the impact score, with each equation being adjusted for the initial score. The results shown in Table 2 indicate that age, duration of disease, and marital status were each associated with significant changes in two of the four health status scores. Education was associated with changes in pain, being widowed was associated with changes in physical function, while sex did not have an effect on any of the scores. These findings demonstrate that none of the demographic variables had a strong or consistent effect across the spectrum of health status scores. There were no significant differences between the results for subjects in the routine care and clinical trial groups.

Discussion

We found little if any deterioration over a five-year period in the health status of patients with established rheumatoid arthritis. In fact, nearly all of the health status measures in this study showed slight improvement, although these changes were not clinically important. This finding of relatively stable health status was true for a group of patients who were initially receiving routine subspecialty care as well as for a group that was initially involved in a drug trial.

These results confirm work by Sherrer and colleagues at Stanford who reported that health status in rheumatoid arthritis is relatively stable after the first few years of disease.[10] In that study, it was reported that disability progressed most rapidly during the early years of disease and then assumed a slow, more linear rate of progression in later years. Over an average follow-up period of 5.6 years in a group of patients with an average disease duration of 10 years at entry,[11] the percentage of their patients with no disability was slightly higher than the percentage with severe disability

(12 per cent versus 11 per cent). Taken together, the findings of that study and this one strongly suggest that health status in rheumatoid arthritis is relatively stable in patients who have had the disease for more than a few years.

Our findings did not indicate that disease duration or demographic factors were consistent determinants of changes in health status. Age, marital status, number of years of disease, and level of formal education were nearly all associated with changes in one or at most two of the four health status scores over the five-year period. However, none of these factors, including level of formal education, proved to be a consistently strong determinant of changes in health status.

In particular, education level was not strongly correlated with change in physical disability. This finding stands in marked contrast to the recently published findings of Pincus and colleagues.[12] It is important to point out, moreover, that demographic variables in general are not very strong predictors of health status. In our study, regression models using demographic and disease duration variables explained approximately 18 per cent of the variability in the four health status scores. In the Stanford study, duration, age, and sex explained less than 25 per cent of the variability.

Our results suggest that health status of patients with established rheumatoid arthritis is more stable than previously thought, particularly if one takes a broad view of health that includes psychological status and pain in addition to physical function. Clinicians who treat patients with rheumatoid arthritis need to consider the pattern of health status change in this disease when deciding on treatment. Aggressive drug therapy in the early stages of disease may be justified since much of the decline in health status appears to occur during this phase. Conversely, patients with established disease may not be good candidates for therapeutic change in the absence of major symptoms or obvious health status declines.

Researchers involved in clinical trials of rheumatoid arthritis also need to consider the implications of these findings. Patients with early disease may be the best candidates for therapeutic trials from both the clinical and statistical perspective since substantial change in outcome is more likely to take place in this group. In addition, sample designs for such trials should seek to gather subjects within a rather narrow range of disease duration so that the results of the trial may be more easily analyzed and interpreted. Finally, and most importantly, broad measures of health status should be included as major outcome measures in any clinical trial of rheumatoid arthritis.

Selection of Elderly Controls Using Random Digit Dialing

GEARY W. OLSEN, DVM, PHD, AND JACK S. MANDEL, PHD, MPH

Abstract: The experience of identifying and soliciting elderly male controls, using a nonclustered random digit dialing procedure in a case-control study, is presented. For elderly controls (ages 65–84) 3.5 times more residential telephone numbers were required than for controls encompassing a much broader age range (ages 40–84). This is a function of the proportion of elderly in the population and their lower response to telephone identification. Elderly controls, age 70 and older, also had lower participation rates. (*Am J Public Health* 1988; 78:1487–1488.)

Introduction

The results from random digit dialing varies among studies for many reasons including the sampling frame used, type of location (urban vs rural), geographical area of the country, age and sex of respondents, method of converting initial telephone screening refusals, and number, placement and degree of sensitive questions to determine eligibility.[1–9] The number of telephone numbers required to obtain controls in pediatric case-control studies has been reported.[8,9] The elderly have the highest proportion of telephone numbers of any age group in the United States.[7] However, the effort required to screen for elderly male controls using random digit dialing compared to younger adult males has not been reported. In this paper we present our experience with a random digit dialing procedure to solicit adult males.

Methods

This was a case-control study to explore dietary factors of potential etiologic significance in the occurrence of pancreatic cancer. Cases were ascertained from death certificates because one year survival is less than 15 per cent.[10] Controls, defined as living White males, ages 40–84, who resided in the seven-county Minneapolis-St. Paul metropolitan area, were frequency matched to cases and ascertained by random digit dialing. The interview was conducted with the control's wife (or other relative) since a surrogate was used to obtain information for the cases.

Initially, cases were divided into five-year age groups so that a similar number of controls could be obtained thus ensuring reasonable comparability on age. An attempt was made to select controls from similar geographic locations within the study area by incorporating the three digit prefix of the cases' telephone numbers into the random digit dialing procedure. The remaining four digits were randomly generated. For each case an initial list of 25 telephone numbers was available. These numbers were called in order and resolved (ineligible, refusal, etc.) before the next number on the list was solicited. Each telephone number was called up to nine times and the calls were evenly distributed among mornings, afternoons, and evenings and weekdays and weekends. If there was no contact after nine calls, the interviewer proceeded to the next telephone number.

An additional variation on random digit dialing was to check each telephone number in a reverse street directory to determine if the number represented a residence or commercial establishment. If a residence, a name was obtained so that the caller could properly address the respondent rather than having to solicit this information as part of the call.

At the initial call information was requested as to whether any males ages 40–84 resided in the household. If there was, a letter was sent which requested their participation. If not, the next number was called until an eligible, willing participant was ascertained. Residences that refused to provide screening information and eligible controls who refused to participate were contacted up to two additional times with letters and follow-up telephone calls. Because of the greater percentage of younger (ages 40–64) men in the population, this group was completed sooner than the older age groups (ages 65–84). Therefore, the age criterion during the enrollment period changed from 40–84 to 65–84. Results from the random digit dialing are presented according to the age groups screened: the initially screened broader age group (40–84) and the narrower, more elderly age group (65–84).

Results

Altogether there were 19,640 telephone calls made to determine the status of 8,936 telephone numbers used in the study (Table 1). The percentage of all telephone numbers called that were residences was similar between the broader age group (52.2 per cent) and the narrower, more elderly age group (55.6 per cent). The mean number of residential telephone numbers required to ascertain a control was 10.3 for the broader age and 34.3 for the more elderly age group. There was a higher percentage of residences that refused to provide the screening information using the broader age screen (6.7 per cent) than the more elderly age screen (5.0 per cent). On average, it took 5.5 hours to identify an eligible control. The following are the percentages (in parentheses) of

TABLE 1—Random Digit Dialing Results

Outcome	Age Group Screened		
	40–84	65–84	Total
Total number of telephone calls needed to determine outcome	9,230	10,460	19,690
Total individual telephone numbers dialed	4,173	4,763	8,936
Numbers dialed:			
Non-working numbers	1,474	1,512	2,986
Non-residential numbers	513	613	1,126
Residential numbers	2,186	2,638	4,824
Ineligible residences	1,828	2,429	4,257
Number of refusals and eligibles:			
Number of residences which initially refused to provide screening information	260 (11.9)*	282 (10.7)	542 (11.2)
Number of initially refused residences which never provided screening information	146 (6.7)	132 (5.0)	278 (5.8)
Number of eligible residences identified	212# (9.7)	77 (2.9)	289 (6.0)
Mean number of telephone numbers per identified eligible residence	19.7	61.9	30.9
Mean number of residential telephone numbers per identified eligible residence	10.3	34.3	16.7

*Percentage of residential numbers in parentheses.
#Fifty-seven per cent were less than 65 years of age.

eligible controls who agreed to participate in the study: less than 60 years of age (80.2), ages 60–64 (82.2), 65–69 (92.6), 70–74 (72.7), 75 and older (69.5).

Discussion

This study demonstrated the greater difficulty in ascertaining only elderly male controls using a non-cluster random digit dialing technique. The non-cluster random digit dialing method has been discussed as straightforward and unbiased[8] although it will contain more telephone numbers that belong to nonresidences than does Waksberg's two-stage cluster method.[9]

Approximately 3.5 times as many residences were contacted in order to identify an eligible elderly control compared to a control from the broader age group. Because of the study design, we were unable to analyze separately the elderly controls ascertained through the use of the broader age range criterion. In spite of this limitation, the present study does illustrate the greater difficulty in identifying and soliciting elderly (ages 65–84) controls using random digit dialing. This is probably a function of the lower proportion of elderly in the population and their lower response to telephone identification.[7] Unfortunately, random digit dialing does not allow for the characterization of those who refuse to provide screening information.

Conceivably, if a cluster random digit dialing procedure was used, it could have reduced the number of calls needed to find the controls. However, there would still have been many more telephone calls necessary to obtain elderly controls. Eligible elderly controls age 70 and older also had a lower study participation rate.

The experience from this study suggests that random digit dialing may not be the most efficient method to identify and solicit elderly controls. An alternative method for soliciting controls among the elderly is through the Health Care Financing Administration which has been used successfully in case-control studies.[12] However, to use these records, the study must be federally funded.

Visits to Physicians Before and After Exposure to Urea Formaldehyde Foam Insulation

KRISTAN A. L'ABBÉ, MSc, JOHN R. HOEY, MD, JAMES HANLEY, PhD, SHOLOM WACHOLDER, PhD, AND ALBERT NANTEL, MD*

Abstract: The average number of visits to a physician made by a sample of 351 residents of homes insulated with urea formaldehyde foam insulation in Montreal in the one year period before exposure was 5.25, and in the year following 5.62, an increase of 7 per cent (odds ratio 1.07, 95%CI=1.00,1.15). The increase in visits in the post insulation year was limited to subjects who had the product installed in the winter (OR=1.48, 95%CI=1.18,1.85), and was not seen for study subjects who insulated their homes during other seasons of the year. (*Am J Public Health* 1988; 78:1489–1491.)

Introduction

The possibility that exposure to urea formaldehyde foam insulation (UFFI) might be detrimental to good health was raised after publication in late 1979, of preliminary results of a study reporting development of nasal carcinoma in rats.[1] By the summer of 1980 homeowners and the general public became concerned about the health effects of UFFI.[2] Studies of residents experiencing high frequencies of allergic reactions, difficulty breathing, nasal stuffiness, headaches, and running eyes were quickly reported in both the scientific[3–5] and lay press, and there was speculation about possible long-term effects: cancer and congenital abnormalities.

Canada and several states in the United States banned the use of UFFI in 1981. Estimates of the number of homes insulated with UFFI are 500,000 in the United States and 100,000 in Canada.

We assessed the health impact of UFFI installation by exploiting the historical records of a universal health insurance system several years after the date of installation of UFFI.

Methods

Study subjects were drawn from the lists of the applicants to a provincial program which offered financial assistance to remove UFFI from homes. Established in 1983, the program required that the "individual in the household most affected by UFFI" be examined by a physician and a report made. There were 2,393 applicants from Montreal. The last group of applicants (453) were not coded by the government agency and were excluded. From the remaining 1,940 applicants we drew a stratified random sample of 351 subjects by sex and 10-year age groups. All subjects gave consent that the information could be used for research purposes.

Demographic information, date of UFFI installation, and Medicare number were obtained from the records of the government program. A subsequent telephone interview established if exposure to UFFI had ended at any time by moving out of the home with UFFI, by removal of UFFI, or through death.

Medical care utilization data were provided by the Régie de l'Assurance-Maladie du Québec (Régie), a universal health insurance system in Québec. Data were supplied for all instances of care received from November 1976 (when this particular type of data storage began) to January 1984. The physician visit required for application to the government program was excluded.

Paired t-tests and logistic regression analyses were done.[6] If the number of visits during two periods are Poisson random variables, then conditioning on the total number of visits during the two periods, the number of visits during one period is a binomial random variable with probability equal to the ratio of its Poisson mean to the sum of the two Poisson means. Thus if the mean number of visits are the same in the period before and after insulation, the proportion during the second period will be 0.5 and the odds ratio associated with exposure will be 1.0. Parameters for seasons of installation were included in the model to check whether the UFFI effect varied according to season of installation of UFFI.

We also adjusted for an annual baseline increase in number of visits to physicians by the general population of Quebec of about 3 per cent over the period of the study.[7] We took this into account by setting the offset in the logistic regression equal to the logit of 1.03, or $\log_e(103/203)/(1-103/203)$.[6]

Results

Of the total sample of 351, two residents were excluded because they had not insulated their homes with UFFI, five subjects because of coding errors, and seven with an unknown or incorrect Medicare number. Of the remaining 337 residents, 323 (96 per cent) completed the study interview (93 per cent of total sample of 349). All subjects with any missing information were excluded, leaving 303 subjects in the analysis (87 per cent of the initial 349 subjects selected for the study).

July 3, 1979 was the mean date of UFFI installation with most installations occurring in the 1978-80 period. The mean end of exposure date was April 1983 with a range of 1980 to 1984, when the final interviews were completed. The mean post exposure period was three years, nine months. The mean delay from time of UFFI installation to application for the assistance program was two and a half years.

Table 1 shows pre and post exposure period physician visits for study subjects. The average number of visits in the one year period before exposure to UFFI was 5.25, and in the year following UFFI installation was 5.62. The differences are accounted for by winter installations rather than installations in other seasons. The increase is most evident in the first and second seasons following initial exposure. Neither

a) Differences in comparison to the same person in the same season, before, and after UFFI exposure.

increases nor decreases in visits are evident for those who had UFFI installed at other times of the year.

This same pattern is seen in Table 2 where odds ratios are presented corresponding to different seasons of UFFI installation. The overall increase in visits after UFFI installation in the winter months is 48 per cent, corresponding to an odds ratio of 1.48 (95% confidence interval = 1.18,1.85). Inclusion of calendar year in the logistic regression model indicated no modification of the UFFI effect by calendar year.

After adjusting the model for the 3 per cent inflationary annual increase in number of visits by the general population, results showed the same pattern with all odds ratio estimates reduced by about 3 per cent. For example, odds ratios for winter were OR=1.43, spring OR=0.95, summer OR=1.02, and autumn OR=1.03.

Discussion

This study shows that utilization of physician services by residents of homes insulated with UFFI increased somewhat in the year following winter insulation (January, February, and March). UFFI installation at other times of the year did not show a similar pattern. While such an effect could be a sampling artefact, it is consistent with the findings that chemical exposure from UFFI may occur as a result of incomplete hardening of the insulation when it is installed in the colder months.[8] Also, chemicals may reach higher concentrations in the interior of homes when ventilation is minimized, as might be the case during the winter.[9–11]

Previous epidemiologic studies on the health effects of UFFI have been limited by the absence of comparison groups,[12,13] possible bias in reporting behavior due to use of self-reported symptoms as an outcome measure,[12–16] and the difficulty of attributing symptoms solely to one environmental exposure.[12–16] By using self-paired comparisons and an objective measure of health status, this study avoids some of these limitations.

Nevertheless, several potential biases may exist in the present study. The use of a sampling frame of homeowners who make use of a government assistance program is not representative. It is likely that self-selection of residents who perceived that they were suffering from exposure to UFFI led to an increased possibility of finding an apparent effect.

In addition, there may have been underreporting of physician visits. However, research on a similar system in Manitoba has shown that the fee-for-service scheme provides valid data on total physician-patient contacts.[17]

Finally, with the records provided, it was not possible to assess the diagnoses for subjects. Possibly only more "serious" health problems which would prompt a person to visit a physician were assessed in this study.

Wife's Level of Education and Husband's Risk of Primary Cardiac Arrest

David S. Strogatz, PhD, David S. Siscovick, MD, MPH, Noel S. Weiss, MD, DrPH, and Gad Rennert, MD

Abstract: Data from a case-control study were analyzed to examine wife's education and risk of primary cardiac arrest in the husband. Men whose wives had more than 12 years of education had 80 per cent the rate of men with less educated wives (odds ratio = 0.8, 95% confidence interval = 0.5, 1.3), after adjustment for risk factors. There was no evidence of a status incongruity effect. These data are inconsistent with reports of positive associations between wife's education and coronary heart disease. (*Am J Public Health* 1988; 78:1491–1493.)

Introduction

Data from the Framingham Study revealed that the risk of coronary heart disease among married men was positively associated with their wives' education.[1] Reports from other populations suggest that this association may apply especially to men who have low education or who demonstrate Type A behavior.[2,3] During the past 20 years, investigations of direct and indirect socioeconomic measures in the United States and Europe typically have found an inverse association with coronary heart disease,[4–9] so a positive relationship with wife's education is a notable exception and may reflect the impact of stress-inducing changes in women's social roles and marital expectations on the home environment.[1,2]

To provide further information on wife's education as a risk factor, we analyzed data from a community-based, case-control study of one major form of coronary heart disease, primary cardiac arrest (PCA). Because this study was restricted to married individuals, it offered the opportunity to examine associations involving wife's education, separately and in combination with husband's education.

Methods

The study design and methods have been described in detail elsewhere.[10,11] PCA was defined as a sudden, pulseless condition without evidence of non-cardiac cause.[12] All cases (fatal and non-fatal) of out-of-hospital PCA in King County, Washington between December 1979 and January 1981 were identified by trained paramedics. The study was restricted to 25-75 year old married residents of King County who had no history of clinically recognized heart disease or activity-limiting co-morbidity (e.g., chronic lung disease, musculoskeletal impairment). For all study subjects, information was obtained in home interviews with spouses. After each case was identified, a control subject meeting the same criteria for eligibility and matched for age (± 7 years), sex, and urban or suburban residence was chosen by random digit dialing.[13] Of eligible subjects identified, 89 per cent of case spouses and 85 per cent of control spouses agreed to participate, producing 163 case-control pairs. Eighty-two per cent of the case-control pairs were male, slightly over half were urban residents, and the average age of cases and controls was 58 and 57 years, respectively.

This analysis was restricted to the 133 male case-control pairs. Education of the men and their wives was classified as

TABLE 1—Distribution of Male Primary Cardiac Arrest Case-Control Pairs According to the Education of Wife: King County, Washington, December 1979–January 1981

		Education of Wife of Control		
		≤12 years	>12 years	Total
Education of Wife of Case	≤12 years	34	42	76
	>12 years	27	30	57
	Total	61	62	133

less than or equal to 12 years (high school graduate or less) or greater than 12 years (beyond high school), yielding approximately equal numbers in each group. Other risk factors which were measured included physical activity (estimated by the Minnesota Leisure-Time Activity Questionnaire),[14] alcohol consumption, current smoking status, and current treatment for hypertension. Odds ratios (OR) were estimated by the conditional maximum-likelihood method using discordant pairs[15] and by logistic regression for matched case-control data.[16] The association between wife's education and PCA in the husband was examined in the absence and presence of other risk factors and by level of the husband's own education, to detect a status incongruity effect.

Results.

The distribution of case-control pairs by wives' education is shown in Table 1. A wife who went beyond high school was less common among cases of PCA (OR = 0.6, 95 per cent CI = 0.4, 1.1). An OR of similar direction, magnitude, and precision was observed for the education of the men themselves (Table 2), with the more educated men at lower risk (OR = 0.7, 95 per cent CI = 0.4, 1.2). When variables representing wife's education and husband's education were entered into a conditional logistic model, the estimated OR for wife's education and PCA changed to 0.7 (95 per cent CI = 0.4, 1.2). The inclusion of a product term combining wife's education and husband's education revealed an absence of interaction; at both levels of husband's education, the estimated OR for wife's education was 0.7. When three categories of wife's education were considered (≤ 12 years, 13-15 years, ≥ 16 years) the OR's with ≤ 12 years as the referent category were 0.7 and 0.6, respectively.

The association between wife's education and primary cardiac arrest in the husband was also examined simultaneously with several risk factors (Table 3). The husband's education and activity level confounded the association slightly. Adjusted for all the risk factors, the OR for wife's education was 0.8 (0.5, 1.3).

Discussion

These results offer some evidence against the hypothesis that wife's education is directly associated with coronary heart disease in the husband.[1] As indicated by the confidence intervals, chance cannot exclude a weak association; also, there could have been unmeasured confounders in our data. If our findings are correct, differences between this study and previous studies may account for the discrepancy. For example, the effect of wife's education may vary for varying forms of coronary heart disease. Men in this study may differ from men studied previously, e.g., if few had Type A behavior.[3,17] However, the proportion of Seattle men with white collar occupations (52 per cent) would not indicate a likely deficit of Type A behavior.[18–20] The Seattle men were born somewhat later (mean year of birth = 1922) than the men of Framingham,[1] Rancho Bernardo,[2] or the Western Collaborative Group Study[3]; possibly secular changes in the social meaning and implications of wife's education have occurred.

Status incongruity and coronary heart disease has been a controversial subject, particularly since status incongruity is not easily defined and analyzed.[21–24] We view status incongruity effects as distinct from effects of the constituent status variables,[25] i.e., the risk for men with more educated wives would represent more than just the expected influence of two separate variables: wife's education and husband's education. These analyses suggest that a less educated husband and a more educated wife do not form a synergistic combination to increase risk of primary cardiac arrest.

TABLE 2—Distribution of Male Primary Cardiac Arrest Case-Control Pairs According to the Education of the Case/Control: King County, Washington, December 1979–January 1981

		Education of Control		
		≤12 years	>12 years	Total
Education of Case	≤12 years	26	38	64
	>12 years	26	43	69
	Total	52	81	133

TABLE 3—Adjusted Odds Ratios Relating Education of Wife to Primary Cardiac Arrest in the Husband: King County, Washington, December 1979–January 1981

Covariate*	Odds Ratio†	95% Confidence Interval
None	0.6	(0.4, 1.1)
Husband's education	0.7	(0.4, 1.2)
Husband's education, smoking	0.7	(0.4, 1.3)
Husband's education, hypertension	0.6	(0.4, 1.1)
Husband's education, physical activity	0.8	(0.5, 1.4)
Husband's education, alcohol consumption	0.7	(0.4, 1.2)
Husband's education, smoking, hypertension, physical activity, alcohol consumption	0.8	(0.5, 1.3)

*The covariates are defined as follows: husband's education (≤12/>12); current smoking status (yes/no); history of treatment for hypertension (yes/no); regular physical activity (above the median/below); monthly alcohol consumption (1–29 drinks/<1 drink; ≥30 drinks/<1 drink).

†Odds ratios were defined to contrast (wife's education >12 years)/(wife's education ≤12 years) and were derived from conditional logistic regression models.

Effects of the North Carolina Prematurity Prevention Program among Public Patients Delivering at New Hanover Memorial Hospital

DEBORAH L. COVINGTON, MS, JOANNE CARL, RN, MPH, JOHN G. DALEY, MD, DEBRA CUSHING, RN, AND M. PAIGE CHURCHILL, BA

Abstract: Twelve per cent of the 847 women who delivered in one hospital prior to implementation of the North Carolina Prematurity Prevention Program had low-birthweight births compared with 9.5 per cent of the 748 women who delivered during the program. Controlling for known risk factors, both low- and very-low birthweight births among Whites (Odds Ratio 2.0 and 3.7 respectively) and very-low-birthweight births among Blacks (OR 2.9) were reduced. (*Am J Public Health* 1988; 78:1493–1495.)

Introduction

In 1984, there were 8.2 neonatal deaths per 1,000 live births in North Carolina compared with 7.3 neonatal deaths per 1,000 live births in the United States in 1983.[1] Because premature delivery and low birthweight are major contributing factors to neonatal mortality,[2,3] the North Carolina Department of Human Resources initiated a statewide program to reduce the risk of prematurity; in January 1985 the obstetric clinic at New Hanover Memorial Hospital implemented this program.

Adapted from programs developed by Papiernik, Creasy, and Hobel,[4–6] the North Carolina Prematurity Prevention Program includes three components: patient identification, patient education, and staff education. Patient identification includes the use of a standardized risk assessment to identify women at risk of preterm labor. Patient education includes intensive education for all patients both on the signs and symptoms of preterm labor and on the need to seek early treatment if preterm labor occurs. Staff education includes in-service training for all staff on the importance of responding promptly to patient complaints of signs and symptoms of preterm labor. Staff are advised to freely admit and observe women suspected to be in preterm labor and, when appropriate, to treat these women using tocolytic agents.

New Hanover Memorial Hospital is a 520-bed community hospital with a university medical center affiliation. It is a regional referral center serving seven counties in the southeastern coastal area of North Carolina. Within the hospital, an obstetric outpatient clinic is staffed by University of North Carolina Medical School faculty, obstetric residents, staff nurses, and County Health Department personnel. Women seeking prenatal care at this facility are mainly young, poorly educated, economically disadvantaged, live in rural as well as urban areas, and about half are Black.

The purpose of this study is to evaluate the effectiveness of the Prematurity Prevention Program in reducing low-birthweight births in the population of women seeking prenatal care at this clinic.

Requests for a single reprint should be sent to Deborah Covington, MS, Research Associate, Area Health Education Center, 2131 South 17th Street, Wilmington, NC 28402. Co-authors Carl, Churchill, and Daley are also affiliated with the Area Health Education Center; Dr. Daley is also with the New Hanover Memorial Hospital in Wilmington, and the Department of Obstetrics and Gynecology, School of Medicine, University of North Carolina at Chapel Hill. Ms. Cushing is with the New Hanover County Health Department, Wilmington, NC. This paper, submitted to the Journal December 17, 1987, was revised and accepted for publication April 27, 1988.

TABLE 1—Exclusion Criteria for the Two Study Groups

	Program Group	Pre-Program Group
Total registered for prenatal care	854	[a]
Aborted, ectopic, or molar pregnancy	31	—
Moved out of region	18	—
Transferred to private physician	11	—
Total delivered[b]	794	910
No prenatal care	32[c]	39
Twin gestation	6	11
Stillbirth	6	11
Livebirth <454 grams	2	2
Total included in analysis	748	847

a) Data on clinic registrants were not available prior to the Prematurity Prevention Program.

b) Labor and Delivery room statistics show that there were 98 fewer clinic staff deliveries in 1986 than in 1984. This could account for the difference between the two groups in the number of deliveries.

c) These women registered for the program, but did not return for prenatal care.

Methods

The study population included 854 women registering for prenatal care at the New Hanover Memorial Hospital obstetric clinic from July 1, 1985 to June 30, 1986.* One hundred and six women were excluded for reasons outlined in Table 1. Data for the 748 women included in the study were obtained by medical record and by birth certificate review.

To obtain comparison data, we used hospital records and birth certificate information for 910 New Hanover Memorial Hospital obstetric clinic patients who delivered prior to initiation of the program, from July 1, 1983 to June 30, 1984.** Using delivery records, we selected only women who received all their prenatal care and were delivered by New Hanover Memorial Hospital clinic staff, but excluded women who aborted, had ectopic pregnancies, or were referred for high-risk deliveries. A total of 847 women were included in the pre-program study group.

We compared the two groups with regard to the percentage of women who had low-birthweight (<2500 grams) and very-low birthweight births (<1500 grams). We used a logistic regression model to determine the independent effect of the program on decreasing low- and very-low-birthweight births while controlling for known risk factors.

*Although the program began in January 1985, the first six months was a trial period. Therefore, we began collecting data six months after program start-up.

**Because staff training took place prior to program start-up, we allowed a six-month interval to control for staff awareness and training effects.

Results

Table 2 compares the two study groups with regard to low birthweight and selected risk factors for low birthweight. With the exception of births less than 2500 grams among Blacks, women in the program were less likely to have a low- or a very-low-birthweight birth than women in the pre-program group. In both racial groups, there were differences in available risk factors between the pre-program and program groups.

Controlling for the potential confounding effects of the risk factors listed in Table 2, a logistic regression model showed that women in the pre-program group were 1.3 times more likely to have a low-birthweight birth than women in the program and 3.2 times more likely to have a very-low-birthweight birth (Table 3). Stratifying the logistic regression analysis by race, we found that White women in the pre-program group were 2.0 times more likely than women in the program group to have a low-birthweight birth and 3.7 times more likely to have a very-low-birthweight birth. Black women in the pre-program group were 2.9 times more likely to have a very-low-birthweight birth than those in the program group. The only other factor contributing to low and very-low birthweight in the logistic regression model was age less than 18 years (OR 1.6, 95% CI=1.2, 2.1 and OR 2.1, 95% CI=1.1, 3.2, respectively).

Discussion

In the initial phase of the Prematurity Prevention Program, results suggest that the program was effective in reducing low- and very-low-birthweight births. We speculate that the reason there was little difference in the percentages of low-birthweight births from pre-program to program group for Black women was that very-low-birthweight births were being delayed by program intervention, but not necessarily being delayed to term. Very-low-birthweight babies tend to have the highest rates of mortality, morbidity, and medical care costs. Delaying very-low-birthweight births even to low

TABLE 2—Low Birthweight and Selected Risk Factors for Low Birthweight by Group and by Race

	Program Group			Pre-Program Group		
	Total[a]	White	Black	Total[b]	White	Black
Number of Births	748	365	374	847	369	468
Low Birthweight	%	%	%	%	%	%
<2500 grams	9.5	6.6	12.5	12.3	12.2	12.2
<1500 grams	0.8	0.6	1.1	2.7	2.2	3.0
Risk Factors						
Black	50.0	—	—	55.3	—	—
Unmarried	57.6	39.2	75.6	50.6	28.0	68.4
Under age 18	12.2	11.5	12.6	13.4	12.2	14.5
Fewer than 12 years of education	44.2	48.2	38.9	49.3	57.9	42.9
Initiated prenatal care after first trimester	77.8	73.2	82.3	80.7	77.7	83.1

a) Includes nine cases categorized racially as "other".

b) Includes eight cases categorized racially as "other" and two as "unknown".

TABLE 3—Relative Odds of Having a Low-Birthweight Birth and Very-Low-Birthweight Birth for Women in the Pre-Program Group by Race Controlling for Certain Risk Factors[a]

		Low Birthweight (<2500 grams)		Very Low Birthweight (<1500 grams)	
	Number of Cases[b]	Odds Ratio	95% CI	Odds Ratio	95% CI
Total[c]	1578	1.3	(1.0, 1.7)	3.2	(2.3, 4.1)
White	728	2.0	(1.5, 2.6)	3.7	(2.2, 5.2)
Black	841	1.0	(0.6, 1.4)	2.9	(1.8, 3.9)

a) Risk factors controlled in the logistic regression model include less than 18 years of age, fewer than 12 years of schooling, initiation of prenatal care after the first trimester of pregnancy, single marital status, and for the total, Black race. Complete data available from author.
b) Cases with missing data were excluded from the analysis.
c) Includes cases categorized racially as "other" or unknown.

birthweight status both decreases mortality and morbidity and reduces the cost of infant care and the drain on critical care nursery resources.

A limitation of our study design is the use of historical controls to evaluate the program. We could not use a prospective randomized design because the program mandated that all women registering for prenatal care in the institution be included in the program; for this reason, we could not use women from the area in and out of the program during the same time period.

Another limitation of our study may be in the selection process. The Prematurity Prevention Program provided us with sufficient identifying information on each clinic registrant with which to select the program group. We had no such information prior to the program and therefore had to use delivery records to select the pre-program group. From these delivery records, we selected only women who had prenatal care at New Hanover Memorial Hospital obstetric clinic and who were delivered by clinic staff. This selection process should yield comparable groups; however, a caveat concerning selection bias seems warranted.

Finally, even though we controlled for certain known risk factors in the analysis, the two groups may differ on other factors for which we could not control.

Johnson Foundation Funds New Program to Enhance Care for Elderly

The Robert Wood Johnson Foundation has launched a new program intended to develop model hospital systems of inpatient geriatric care in the United States. The initial grant of $392,000 was recently awarded to the Veterans Administration Medical Center in Denver — the first of four pilot projects to be funded under a $1.6 million national initiative. The Denver-based pilot will utilize the VA Medical Center's expertise in geriatrics, and also involve the participation of several major hospital and health provider organizations in Colorado.

Many elderly lack access to physicians trained in geriatrics. This program is designed to develop models to help community physicians and hospitals provide better care for the growing numbers of elderly patients in need of special attention. Interdisciplinary teams of medical personnel will be formed to address the varied and interrelated needs of the high-risk elderly patients.

A major focus of the Denver project will be to:

- Identify, upon admission, those elderly patients who are most at risk of functional decline during their hospitalization;
- Develop clinical management strategies to prevent problems that may arise during the hospital stay of these high-risk patients;
- Educate and enhance awareness of the special needs of the elderly patient in each participation institution and in the local community.

Dental Care and Dental Health: NHIS

MARY GRACE KOVAR, DRPH, SUSAN JACK, MS, AND BARBARA BLOOM, MPA

In 1986, 57 per cent of individuals in the United States age two years or over had made at least one visit to a dentist within a year compared with 55 per cent in 1983.

Receiving dental care is strongly associated with the ability to pay for it. People in families with more income were more likely to visit a dentist than people in families with less income; 74 per cent of the individuals in families with annual incomes of $35,000 or more had at least one dental visit in 1986, in contrast with 41 per cent in families with incomes of less than $10,000.

Having private dental insurance was associated with the use of dental care regardless of income. Individuals and families with private dental insurance were more likely to visit a dentist (70 per cent) than those without insurance (50 per cent). Those with private dental coverage had higher visit rates (2.6 versus 1.7 visits per person per year in 1986) and a higher proportion reported that their last visit was for a checkup. Such differences between those with and without private dental insurance persisted within each income category.

This information is from a recent report based on data from the 1986 National Health Interview Survey (NHIS).[1] It is the first time questions on dental care and dental health had been asked on that survey since 1983. Some questions were included from earlier surveys to examine change over time; new questions addressed such matters as dental insurance and children's use of prophylaxis.

The NHIS is a continuing household interview survey of the civilian noninstitutionalized population in the United States. US Bureau of the Census interviewers visit a probability sample of households each week. In 1986, 23,838 households containing 62,052 persons were interviewed. The household response rate was 96.5 per cent: most of the noninterviews were because no one was at home. A responsible member of the household answered the questions for children and for other adults in the family who were not at home.

Although access to dental care appears to have improved between 1983 and 1986, inability to pay, lack of awareness about the importance of dental care, or reluctance to seek dental care leave many people without adequate care.

Elementary school-age children need good dental care and 71 per cent of the children ages 5–11 years had seen a dentist at least once during the year prior to the interview. However, only 39 per cent had made two or more visits to a dentist. Over one-fourth of the children in this age span had not seen a dentist within a year, including 11 per cent who had never seen a dentist (Table 1). Forty per cent or more of the Black, Mexican American, or poor children had inadequate care (defined as no visit within a year). If inadequate is defined as no visit within six months, the percentages are much higher; only 44 per cent of the children 5–11 years of age were reported to have had a visit that recently. Even in families with incomes of $35,000 or more, 13 per cent of the children this age had not seen a dentist within a year and 39 per cent had not seen a dentist within six months.

TABLE 1—Children Ages 5–11 Years with Inadequate Dental Care

	No Visit	
	Within a year	Ever
	Per cent of Children	
All Children	28.3	11.4
Family Income less than $10,000	43.4	17.4
Mexican American	49.4	24.3
Black	41.3	16.9

SOURCE: 1986 National Health Interview Survey

According to their parents, 93 per cent of the children ages 2–16 used fluoride toothpaste, 8 per cent used fluoride supplements, and 13 per cent used a fluoride mouthrinse at home. About 7 per cent (12 per cent of the 9–11 year-olds) had received dental sealants.

About 11 per cent of the children were reported to be in fluoride mouthrinse programs at school, although the percentage of elementary school-age children in such programs is higher (Table 2). These programs are designed to serve low-income children and the data show that low-income

TABLE 2—Children's Participation in School Mouthrinse Programs

Age of Child (years)	Family Annual Income				
	All Incomes	Under $10,000	$10,000 –19,999	$20,000 –34,999	$35,000 or more
	Per Cent of Children				
2–16	10.5	13.5	12.8	10.7	7.5
5–8	15.5	18.8	18.6	15.8	11.2
9–11	19.8	22.4	24.4	20.2	15.3

SOURCE: 1986 National Health Interview Survey

children were more likely than upper-income children to be participating in such programs. However, only a minority of the children in low-income families were reported to be participating in fluoride mouthrinse programs at school. The report does not show whether those children had seen a dentist.

In contrast with children and younger adults, relatively few older people receive dental care. Only 42 per cent of the people age 65 and over had seen a dentist within a year; the critical distinction was whether the older person had any natural teeth. Among older people with teeth, 61 per cent had seen a dentist within a year; only 9 per cent of the older people with no remaining natural teeth had done so. The majority (71 per cent) of the edentulous older people had not seen a dentist for at least five years.

Dental care is an important, but sometimes neglected, part of total health care. People seldom die for lack of dental care, but the quality of their lives can be compromised by the lack of appropriate dental care. Children who fail to have their problems taken care of grow into adults with decayed, missing, or malocclude teeth. Older people who have not received appropriate care may suffer from periodontal disease, missing teeth, or poorly fitting dental appliances.

While the data in the report show that most people do receive dental care, they also document that significant groups of people do not; this can be useful for designing programs to reach those people.

Kellogg Foundation Invites Applications for 1989 Fellowship Awards

The W. K. Kellogg Foundation recently announced the availability of its Kellogg National Fellowship awards for 1989. Initiated in 1980, the program is designed to prepare leaders who can function effectively and knowledgeably in dealing with complex problems where narrow expertise is not sufficient. It seeks to involve professional men and women in the earlier years of their careers who are interested in developing interdisciplinary and cross-cultural perspectives on contemporary human and social problems.

The Fellowship awards will be made on behalf of up to 50 individuals of exceptional merit and competence who have exhibited leadership potential in their community, organization or profession. To be eligible for the three-year program, an applicant must be a US citizen, accept responsibility to participate in *all* activities related to the program, and receive 25 per cent released time from his/her employer to carry out a non-degree, self-directed learning plan to expand personal horizons beyond the confines of a chosen profession. Individuals employed in both the non-profit and for-profit sectors may apply.

In addition to completion of the learning plan, Fellows must attend seven seminars sponsored by the Foundation, one of which is a two-week seminar in Latin America, with all others being one-week seminars in various cities in the US. Attendance is required at *all* seminars.

The award includes $35,000 for the development and completion of the learning plan and $5,000 to be used only for travel expenses incurred while participating in required seminars. In addition, 12-1/2 per cent of the Fellow's salary, up to $24,000 over the three years, will be reimbursed to the sponsoring/employing institution. Fellows not employed by a non-profit organization are not eligible for the salary reimbursement; however, in certain cases a monthly stipend of $300 may be available.

The deadline for applications is December 19, 1988. To obtain an application package or additional information, contact: Applications, Kellogg National Fellowship Program, W. K. Kellogg Foundation, 400 North Avenue, Battle Creek, MI 49017-3398. Tel: (616) 968-1611.

Nix FOR LICE®
CREME RINSE
permethrin 1%

Rx
Nix
Disp 2 fl oz
Sig as directed on bottle label
Tim Smith, MD

PEDICULICIDAL/OVICIDAL ACTIVITIES: *In vitro* data indicate that permethrin has pediculicidal and ovicidal activity against *Pediculus humanus* var. *capitis*. The high cure rate (97-99%) of Nix in patients with head lice demonstrated at 14 days following a single application is attributable to a combination of its pediculicidal and ovicidal activities and its residual persistence on the hair which may also prevent reinfestation.

INDICATIONS AND USAGE: Nix is indicated for the single-application treatment of infestation with *Pediculus humanus* var. *capitis* (the head louse) and its nits (eggs). Retreatment for recurrences is required in less than 1% of patients since the ovicidal activity may be supplemented by residual persistence in the hair. If live lice are observed after at least seven days following the initial application, a second application can be given.

CONTRAINDICATIONS: Nix is contraindicated in patients with known hypersensitivity to any of its components, to any synthetic pyrethroid or pyrethrin, or to chrysanthemums.

WARNING: If hypersensitivity to Nix occurs, discontinue use.

PRECAUTIONS:

General: Head lice infestation is often accompanied by pruritus, erythema, and edema. Treatment with Nix may temporarily exacerbate these conditions.

Information for Patients: Patients with head lice should be advised that itching, redness, or swelling of the scalp may occur after application of Nix. If irritation persists, they should consult their physician. Nix is not irritating to the eyes; however, patients should be advised to avoid contact with eyes during application and to flush with water immediately if Nix gets in the eyes. In order to prevent accidental ingestion by children, the remaining contents of Nix should be discarded after use.

Combing of nits following treatment with Nix is not necessary for effective treatment. However, patients may do so for cosmetic or other reasons. The nits are easily combed from the hair treated with Nix after drying.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Six carcinogenicity bioassays were evaluated with permethrin, three each in rats and mice. No tumorigenicity was seen in the rat studies. However, species-specific increases in pulmonary adenomas, a common benign tumor of mice of high spontaneous background incidence, were seen in the three mouse studies. In one of these studies there was an increased incidence of pulmonary alveolar-cell carcinomas and benign liver adenomas only in female mice when permethrin was given in their food at a concentration of 5000 ppm. Mutagenicity assays, which give useful correlative data for interpreting results from carcinogenicity bioassays in rodents, were negative. Permethrin showed no evidence of mutagenic potential in a battery of *in vitro* and *in vivo* genetic toxicity studies. Permethrin did not have any adverse effect on reproductive function at a dose of 180 mg/kg/day orally in a three-generation rat study.

Pregnancy: *Teratogenic Effects:* Pregnancy Category B: Reproduction studies have been performed in mice, rats, and rabbits (200-400 mg/kg/day orally) and have revealed no evidence of impaired fertility or harm to the fetus due to permethrin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the evidence for tumorigenic potential of permethrin in animal studies, consideration should be given to discontinuing nursing temporarily or withholding the drug while the mother is nursing.

Pediatric Use: Nix is safe and effective in children two years of age and older. Safety and effectiveness in children less than two years of age have not been established.

ADVERSE REACTIONS: The most frequent adverse reaction to Nix is pruritus. This is usually a consequence of head lice infestation itself, but may be temporarily aggravated following treatment with Nix. 5.9% of patients in clinical studies experienced mild temporary itching; 3.4% experienced mild transient burning/stinging, tingling, numbness, or scalp discomfort; and 2.1% experienced mild transient erythema, edema, or rash of the scalp.

DOSAGE AND ADMINISTRATION:

Adults and Children: Nix is intended for use after the hair has been washed with shampoo, rinsed with water and towel dried. Apply a sufficient volume of Nix to saturate the hair and scalp. Nix should remain on the hair for 10 minutes before being rinsed off with water. A single treatment is sufficient to eliminate head lice infestation. Combing of nits is not required for therapeutic efficacy, but may be done for cosmetic or other reasons.

SHAKE WELL BEFORE USING.

HOW SUPPLIED: Nix (Permethrin) 1% (wt./wt.) Creme Rinse is supplied in plastic squeeze bottles that contain 2 fl. oz. weighing 56 g. (NDC-0081-0780-81)
Store at 15°-25°C (59°-77°F).

Patterns of Sexual Behavior and Condom Use in a Cohort of Homosexual Men

MARTIN T. SCHECHTER, MD, PHD, KEVIN J. P. CRAIB, MMATH, BRIAN WILLOUGHBY, MD, CCFP, BRUCE DOUGLAS, MD, FRCPC, W. ALASTAIR MCLEOD, MD, FRCPC, MICHAEL MAYNARD, MD, PETER CONSTANCE, MD, AND MICHAEL O'SHAUGHNESSY, PHD

Abstract: To measure the magnitude of risk reduction within a cohort of homosexual men, questionnaire responses in April 1984–March 1985 were compared to those in October 1986–September 1987. A total of 361 subjects were eligible (231 seronegative, 130 seropositive). The annual number of sex partners declined significantly from a median of 8.0 to 5.0 with no difference between the serologic groups. The number of subjects reporting no receptive anal intercourse increased as did condom use during anal receptive intercourse. More seronegatives than seropositives subjects reported *no* condom use during receptive anal intercourse with *regular* partners (45.7 per cent versus 23.4 per cent), and with *casual* partners (14.9 per cent versus 1.5% percent). Among subjects with the most casual sexual contact at the second visit, 33.3 per cent of seronegatives and 29.2 per cent of seropositives did not report usual condom use during receptive anal intercourse with casual partners. Although we have documented marked risk reductions, safe sex practices are still not universal, and a few individuals continue to put themselves at extremely high risk. (*Am J Public Health* 1988; 78:1535–1538.)

Introduction

In the absence of an effective vaccine against *human immunodeficiency virus* (HIV), primary prevention efforts must center on modifying behaviors associated with its transmission. Thus, community groups and public health agencies have concentrated their efforts to varying degrees on promoting both reductions in the number of sex partners and in the frequency of anal intercourse, as well as increases in the use of condoms and in the practice of other safe sexual activities. The degree to which such changes have occurred has only recently been assessed and the effect of knowledge of HIV serologic status on risk reduction remains unclear. We report here on changes in sexual practices and condom use in our ongoing cohort study of homosexual men.

Methods

The methods and aims of the Vancouver Lymphadenopathy-AIDS Study (VLAS) have been described in detail previously.[1,2] Briefly, the VLAS is an ongoing prospective study of over 700 homosexual men who were recruited from six general practices in central Vancouver, British Columbia during the period November 1982 to February 1984. Subjects have been returning for follow-up visits approximately every six months since enrollment. The visit frequency has been reduced to once per year in the last cycle. During each visit, subjects complete a detailed self-administered questionnaire. In addition, each study subject undergoes a complete physical examination and blood samples are drawn for immunologic and HIV antibody testing. Antibody testing is carried out at the National Reference Laboratory at the Laboratory Center for Disease Control in Ottawa utilizing ELISA (enzyme linked immunosorbent assay) with equivocal results further assessed by Western Blot. Some participants may have additional blood samples drawn for HIV antibody testing between study visits at the discretion of their physicians. All participants are counseled by their physicians to adopt safer sex guidelines including reduction in the number of sex partners and avoidance of unprotected intercourse.

Subjects were eligible for this analysis if they completed their third visit during the period April 1984–March 1985 (EV) and their seventh visit during October 1986–September 1987 (LV). The third visit was chosen for the baseline because serologic results were not available until this time and the seventh visit was the most recently completed at the time of analysis.

As of October 1987, 58 cases of AIDS (acquired immune deficiency syndrome) had been diagnosed in our study according to Centers for Disease Control (CDC) criteria. Seropositive subjects for the present analysis were defined as those eligible subjects who were seropositive at EV and who had remained AIDS-free as of October 1987. It should be noted, however, that 14 per cent of the seropositive group at EV had an AIDS-related condition as defined by a helper cell (CD4) count below 400 and/or two or more of the following symptoms: fever, weight loss, fatigue, diarrhea, arthralgia, thrush, cough unrelated to smoking, or dyspnea. Seronegative subjects were defined as those who were seronegative at EV. It was recognized that the seronegative group would contain individuals who seroconverted between visits and were therefore seropositive at the time of LV.

Patterns of sexual behavior were measured using questionnaire items pertaining to the number of different sexual partners in the previous 12 months, the frequency of various sexual practices during this period, and condom use during these practices. At LV, a distinction was made between regular (at least one sexual encounter per month) and casual partners.

Statistical analyses of the data were carried out using non-parametric methods because inspection revealed the distribution of number of sexual partners to be non-normal. All reported p-values are two-sided. For all paired comparisons, subjects with incomplete or missing information regarding the variable of interest were excluded from the analysis.

Results

A total of 361 subjects completed their third and seventh

visits within the defined time periods. Those not eligible included 97 whose third and/or seventh visits fell outside the defined periods, 45 who had not yet completed their seventh visit, 58 who had developed AIDS by October 1987, 79 who had moved away, 89 who had withdrawn from the study, and one who died of unrelated causes. Of the 361 eligible subjects, 231 (64.0 per cent) were seronegative at EV, and 130 (36 per cent) were seropositive; 27 (11.7 per cent) of the 231 seronegative subjects seroconverted during the period between visits. The median interval duration between the EV and LV for all 361 subjects was 28 months (range = 20–42), 29 months for the seronegative group, and 27 months for the seropositive group. The median ages at EV were identical (34 years) for the two groups.

As seen in Table 1, there was a decline in the reported number of annual sexual partners between the two visits from a median of 8.0 to 5.0. Of the 361 subjects, 246 (68.1 per cent) reported a reduction in the number of sexual partners, 19 (5.2 per cent) reported no change, and 96 (26.6 per cent) reported an increase. Declines were noted in both the seronegative and seropositive groups. It is noteworthy that the decline in numbers of partners was similar whether or not an AIDS-related condition as defined above was present at EV.

To control for the higher number of sexual partners at baseline in the seropositives, we restricted the analysis to subjects who reported more than the median number (8) of sexual partners at EV (Table 2). Essentially equal declines were noted in both groups.

As seen in Table 3, there was a decline in the frequency of receptive anal intercourse between EV and LV. At EV, 28.1 per cent of seronegatives and 16.9 per cent of seropositives reported none of this practice in the prior year. At LV, these proportions had risen to 45.3 per cent and 35.6 per cent, respectively with regular sexual partners and 74.5 per cent and 36.9 per cent, respectively with casual partners. However, 6.6 per cent of seronegatives and 31.1 per cent of seropositives reported receptive anal intercourse in at least 30 per cent of casual sexual encounters. Seronegatives were much more likely to not practice receptive anal intercourse with casual than with regular partners at LV but no such differences were seen with seropositives.

Table 4 demonstrates a marked increase between the visits in the use of condoms during receptive anal intercourse. At EV, only 3.6 per cent of seronegatives and 3.7 per cent of seropositives reported condom use in more than 30 per cent of receptive anal acts. At LV, these proportions had risen to 34.4 per cent and 63.9 per cent, respectively with regular partners and 72.3 per cent and 81.5 per cent, respectively with casual partners. It is noteworthy that a higher proportion of seronegative subjects than seropositive subjects reported never using condoms during receptive anal intercourse with casual partners (14.9 per cent vs 1.5 per cent; $p = 0.007$).

As seen in Table 5, among those in the upper 50 per cent of casual contact, 33.3 per cent of seronegatives and 28.2 per cent of seropositives reported they used condoms in less than 60 per cent of receptive anal exposures to casual partners.

TABLE 1—Reported Numbers of Sexual Partners in Past Year at EV and LV by Serologic Group

Group	EV	LV	LV-EV*	P-Value**

Discussion

There are several caveats which should be recognized at the outset concerning these data. Our original intent in recruiting participants through general practitioners was to avoid potential bias associated with recruitment through sexually transmitted disease clinics or secondary referral centers. Nevertheless, it must be recognized that gay men who choose to attend medical practices that provide care to

†Restricted to those reporting at least some receptive anal intercourse with a casual partner.

large numbers of gay men may not accurately reflect the homosexual community at large. Furthermore, the mere participation in a prospective study involving repeated questionnaires, physical examinations, serologic testing, and counseling by committed practitioners can be expected to have additional effects on behavior that may not have occurred outside the context of the study. This represents a form of surveillance bias in which the very act of observation influences the behavior being observed. In addition, questions naturally arise concerning the reliability and validity of information obtained by questionnaire regarding sexual activity. However, some reports suggest that both the interviewer-administered and self-administered questionnaire can provide reasonably reliable data concerning sexual behavior in gay men when the period of recall is relatively short.[3,4] The data analyzed in this study always pertained to sexual behavior in at most the year prior to questionnaire completion. There remains the question of the definition of the seronegative group. We defined the latter to include those individuals who were HIV antibody negative at the time of EV which resulted in the inclusion of 27 individuals who had seroconverted between EV and LV. However, as it was our intent to study the relation of serologic status and *subsequent* behavior change, we felt that this definition was the most appropriate. Any definition requiring persistent seronegativity throughout the duration of observation would impose constraints on behavioral variables during this period and artifactually influence the behavior change under study.

TABLE 5—Frequency of Condom Use During Receptive Anal Intercourse with Casual Partners at LV by Serologic Group Among Those Reporting Receptive Anal Intercourse and More Than Five Casual Partners

Sexual Behavior	Frequency of Condom Use*	Seronegative** n (%)	Seropositive** n (%)
Receptive anal intercourse with casual partners at LV	Never	3 (10.0)	0 (0.0)
	Infrequent	4 (13.3)	8 (16.7)
	Often	3 (10.0)	6 (12.5)
	Usually	20 (66.7)	34 (70.8)

*Infrequent = 1–30% of episodes of receptive anal intercourse; Often = 31–60% of episodes of receptive anal intercourse; Usually = >60% of episodes of receptive anal intercourse.

The present data document marked changes in sexual behavior in this cohort over a 28-month period, suggesting at least some success for ongoing educational initiatives. Our results are consistent with behavioral change which has been reported in several other studies of homosexual men[5–13] and which may now be having beneficial effects on HIV transmission. Winkelstein, *et al*, demonstrated progressive declines in seroconversion rates in a seronegative cohort which they attributed, at least in part, to behavior change.[5] We have recently found similar declines in seroconversion among initially seronegative men in our cohort, with five successive annual seroconversion rates from November 1982 through October 1987 of 3.9, 9.8, 7.3, 4.2, and 0.9 per cent respectively.*

Our finding that the decline in number of sexual partners was comparable in the seronegative and seropositive groups is consistent with the observation of Fox, *et al*,[12] that disclosure of serologic status did not markedly influence subsequent numbers of partners in a cohort of homosexual men. The fact observed here and elsewhere[12,13] that the marked overall behavior change exceeded any differences between serologic groups suggests that the effects of societal influences, such as community education and media coverage, may have outweighed any marginal additional effect of knowledge of serologic status. We did observe some differences, however, between the serologic groups. Although seronegatives practiced receptive anal intercourse with casual partners less often than did seropositives, it was disconcerting to note that when they did engage in this practice, seronegatives utilized condoms less often than did seropositives. Although it may be that seronegatives were more selective in the choice of their casual partners, the possibility remains as suggested by others[12,13] that some seronegatives may infer from their negative status some form of protection and this may act as a disincentive to behavior change.

Our data highlight an important fact concerning sexual behavior in this population often overlooked in studies of temporal change. It is that it is potentially misleading to measure overall change in certain variables such as numbers of partners or condom use without reference to the type of partner or the sexual activity in question. Sexual encounters can vary in their risk of HIV transmission from the ongoing sexual encounters of two mutually monogamous seronegative partners at one end of the spectrum, to receptive anal intercourse with casual or anonymous partners of unknown serology at the other. Seronegatives appeared to adjust the type of sexual practice to the partner in that they were much more likely to never practice receptive anal intercourse with casual partners than with regular partners. Furthermore, at the recent visit, seronegatives were more likely to use condoms during receptive anal intercourse with casual partners than with regular partners. Failure to distinguish between types of partners would have obscured these differences and would have attenuated the change observed with casual partners where safer practices are most critical. Nevertheless, it was disappointing to observe that even at the recent visit, as many as 15 per cent of seronegatives never use condoms during receptive anal intercourse with casual part-

* Schechter MT, Willoughby B, Craib KJP, *et al*. Unpublished data, 1988.

ners and only 64 per cent of this group report the usual use of condoms during this practice. While it is a small proportion of seronegatives who report continuing receptive anal intercourse with casual partners, these individuals continue to place themselves at extremely high risk of HIV infection and probably account for why new infections, although slowing, are still continuing to appear. Also, seropositives with symptoms or low helper cell counts, who may be the most infectious to others,[14] did not lower their numbers of partners to any greater degree than well seropositives. The barriers to behavior change[15,16] at work in these subgroups and in other areas where behavior change has been less marked[17,18] need to be studied so that individuals at continuing high risk can be effectively targeted.

US Government Issues Report on Status of Organ Transplantation

The US Government issued its first annual report on the scientific and clinical status of organ transplantation in late summer. The essence of the report, based on the 1986 data, is that "significant advances are being made in the field of organ transplantation," and there has been a dramatic rise in the number of people receiving transplants as well as the number of people on waiting lists. According to the report:

- One-year patient survival is 96 per cent for recipients of kidneys from living donors, and 91 per cent for recipients of cadaveric kidneys;
- One-year graft survival rates are about 88 per cent for recipients of kidneys from living donors, and 71 per cent for recipients of cadaveric kidneys;
- The probability of survival for at least one year after heart transplantation is about 85 per cent when triple drug therapy is used to suppress the immune system. Triple drug therapy usually involves cyclosporine, azathioprine and corticosterioids.
- The number of people benefitting from organ transplants—kidney, heart, liver, heart-lung, or pancreas transplants—was about 11,500 in 1986. More than 10,500 remained on waiting lists at the end of the year.

Copies of the new *Report on the Scientific and Clinical Status of Organ Transplantation* may be obtained from: Division of Organ Transplantation, Rm 9-31, Health Resources and Services Administration, US Public Health Service, DHHS, 5600 Fishers Lane, Rockville, MD 20857. Tel: (301) 443-7577.

Racial/Ethnic Differences in the Risk of AIDS in the United States

RICHARD M. SELIK, MD, KENNETH G. CASTRO, MD, AND MARGUERITE PAPPAIOANOU, DVM, PHD

Abstract: We analyzed the variation in the risk of AIDS in US Blacks, Hispanics, and other racial/ethnic groups relative to that in Whites (non-Hispanic) by geographic area and mode of acquiring HIV infection, based on data reported between June 1, 1981 and January 18, 1988 to the Centers for Disease Control and 1980 US census data. Relative risks (RRs) in Blacks and Hispanics were highest in the northeast region, and higher in suburbs than in central cities of metropolitan areas. RRs in Blacks and Hispanics were greatest for AIDS directly or indirectly associated with intravenous-drug abuse by heterosexuals (range: 5.7–26.9) and were also high for AIDS associated with male bisexuality (range: 2.5–4.8), suggesting that these behaviors may be more prevalent in Blacks and Hispanics than in Whites. Prevention strategies should take into account these racial/ethnic differences. (*Am J Public Health* 1988; 78:1539–1545.)

Introduction

Although most patients reported with acquired immunodeficiency syndrome (AIDS) in the United States are non-Hispanic White homosexual males, the perception of AIDS as predominantly a disease of gay White men has changed. The risk of AIDS is higher in American Blacks and Hispanics and the racial/ethnic differences in risk are greatest in association with intravenous-drug abuse (IVDA) by heterosexuals.[1–9] We present here the results of a study to determine more precisely the magnitude of the association between AIDS and racial/ethnic group for different means of acquiring human immunodeficiency virus (HIV) infection and the variation in this association by geographic area and over time.

Methods

To measure the risk of AIDS in a given racial/ethnic group, we used the cumulative incidence (number of AIDS cases reported in that group per million population of the same group). AIDS cases were those meeting the case definition[10] in residents of the United States (excluding US territories) reported to the Centers for Disease Control (CDC) between June 1, 1981 and January 18, 1988. Reporting of AIDS cases by health care providers is mandatory in all states. CDC receives data on these cases from the health departments of state and selected local governments. The population of each racial/ethnic group was that reported by the US Bureau of the Census for 1980.[11]

We used relative risk (RR) to examine the magnitude of the association between AIDS and racial/ethnic group. The RR in a given group was the ratio of the cumulative incidence of AIDS in that group to the cumulative incidence in a reference group, in this instance being Whites who are not Hispanic. We stratified the analyses by sex and age group (men, women, and children <15 years of age).

The 99 per cent confidence intervals around RRs were approximated by the first-order Taylor series method.[12] For RRs equal to zero, the upper limits of the confidence intervals were estimated by the method of Fleiss.[13]

We classified AIDS patients in a hierarchy of exposure categories according to their presumed means of acquiring HIV infection. Patients with more than one possible means of acquisition were classified only in the exposure category listed first in the hierarchy, except for the combination of IVDA and male homosexuality/bisexuality.

We also stratified the analyses by region,[11] population of metropolitan areas, and residence inside or outside the central cities of selected metropolitan areas. For analysis by residence inside or outside the central cities of metropolitan areas, we selected the 16 most populous SMSAs (≥2 million inhabitants each) that had central cities.

To assess trends in RRs by exposure category from 1979 through 1987, we used weighted least-squares regression analysis (with the inverse variances of the quarter-yearly RRs as weights).[15] Only RRs significant at the $p<0.01$ level were analyzed.

Results

CDC received reports of 50,830 AIDS patients in the United States between June 1, 1981 and January 18, 1988. Of the 50,704 (99.8 per cent) with specified race/ethnicity, 60.9 per cent were classified as White, 25.5 per cent as Black, 12.9 per cent as Hispanic, and 0.7 per cent as Other. In contrast, of the US population (226,545,805), 79.6 per cent were classified as White, 11.5 per cent as Black, 6.4 per cent as Hispanic, and 2.5 per cent as Other. Overall, the risk (cumulative incidence) of AIDS in Blacks and Hispanics was almost three times as great as that in Whites. By sex and age group, the risks of AIDS in Black and Hispanic men were 2.8 and 2.7 times, respectively, that in White men; the risks in Black and Hispanic women were 13.2 and 8.1 times that in White women; and the risks in Black and Hispanic children were 11.6 and 6.6 times that in White children (Table 1). The risks in other racial/ethnic groups were less than the risk in Whites.

Analysis by Exposure Category

The proportion of AIDS cases associated with IVDA by heterosexuals (including their sex partners and children) was 39.7 per cent in Blacks and 38.7 per cent in Hispanics, compared with 6.3 per cent in Whites, 4.0 per cent in Asians and Pacific Islanders, and 19.6 per cent in American Indians, Eskimos, and Aleuts. These IVDA-exposure categories were associated with the highest RRs in Blacks and Hispanics, ranging from 5.7 to 26.9 (Table 2).

The risk of AIDS in exclusively homosexual men without a history of IVDA was 1.3 and 1.7 times as great in Black and Hispanic men, respectively, as in White men (Table 3). For bisexual men with AIDS, the RRs were higher (3.6 and 2.5 in Blacks and Hispanics, respectively). The proportion of bisexual men among homosexual and bisexual men with

TABLE 1—Cumulative Incidence* and Relative Risk (RR)† of AIDS, by Racial/Ethnic Group

Sex and Age Group	Racial/Ethnic Group	AIDS Cases	Cumulative Incidence*	RR	(99% Confidence Interval)
Men,					
≥15 years	White	29,614	432.9	1.0	
	Black	10,569	1,233.7	2.8	(2.8, 2.9)
	Hispanic	5,783	1,179.7	2.7	(2.6, 2.8)
	Other	317	123.1	0.4	(0.3, 0.4)
Women,					
≥15 years	White	1,090	14.7	1.0	
	Black	1,946	193.4	13.2	(12.0, 14.5)
	Hispanic	596	118.5	8.1	(7.1, 9.2)
	Other	26	12.6	0.9	(0.5, 1.4)
Children,					
<15 years	White	183	4.9	1.0	
	Black	423	56.6	11.6	(9.3, 14.6)
	Hispanic	151	32.3	6.6	(5.0, 8.8)
	Other	6	3.9	0.8	(0.3, 2.3)
Total	White	30,887	171.4	1.0	
	Black	12,938	495.6	2.9	(2.8, 3.0)
	Hispanic	6,530	447.0	2.6	(2.5, 2.7)
	Asian or Pacific Islander	298	83.9	0.5	(0.4, 0.6)
	American Indian, Eskimo, or Aleut	51	35.6	0.2	(0.1, 0.3)

*AIDS cases reported from June 1, 1981 to January 18, 1988 per million population of same race/ethnicity.
†Reference group for relative risk: Non-Hispanic Whites

AIDS was greater in Blacks (30 per cent) and Hispanics (20 per cent) than in Whites (14 per cent). This pattern was reflected in the risk of AIDS in women whose sex partner was a bisexual man, which was 4.6 and 3.6 times as great in Black and Hispanic women, respectively, as in White women. The addition of a history of IVDA increased the racial/ethnic RRs associated with male homosexuality (Table 3).

The risk of AIDS associated with prior receipt of a blood transfusion was 2.5 times as great in Black and Hispanic children as in White children. In addition, the risks of AIDS in transfused women, in male sex partners of transfused women, and in children of transfused women were higher in Blacks than in Whites (Table 4). The only category in which Blacks had a lower risk of AIDS than Whites was coagulation disorders (e.g., hemophilia), in which the RR in Black men was 0.4 (99 per cent confidence interval: 0.3, 0.8).

The risks of AIDS in Blacks and Hispanics were substantially higher than the risk in Whites for exposure categories associated with undetermined means of acquiring HIV infection, including categories involving heterosexual and perinatal transmission from persons with undetermined means of acquiring HIV infection (Table 5).

Analysis by Geographic Area

In general, the RRs in Blacks and Hispanics were greatest in the northeast US and least in the west (Table 6). In the west, the risk of Hispanics was actually less than that in Whites for AIDS in exclusively homosexual men and for AIDS overall. In all regions, the risk in other groups (e.g., Asians) was less than the risk in Whites for AIDS in homosexual men and overall; for no exposure category was it significantly greater than the risk in Whites. The northeast was the only region in which most AIDS cases in Blacks and Hispanics (54 per cent and 57 per cent, respectively) were associated with IVDA by heterosexuals (including their sex partners and children).

Of AIDS patients with a reported city or county of residence (97 per cent), 95 per cent resided in 314 of the 318 SMSAs recognized by the Bureau of the Census; 5 per cent resided outside SMSAs. The 168 SMSAs in the smallest population category (50,000–250,000 population) contained 10 per cent of the US population and accounted for 3 per cent of AIDS cases, whereas the 16 SMSAs in the largest population category (>2,000,000 population) contained 27 per cent of the US population and accounted for 62 per cent

TABLE 2—Relative Risk* of AIDS Associated with History of Intravenous-Drug Abuse (IVDA), by Racial/Ethnic Group and Exposure Category

Exposure Category	White*	Black	Hispanic	Other
Adults with IVDA:				
Homosexual or bisexual men	1.0	3.0 (2.7, 3.3)	2.3 (2.0, 2.6)	0.2 (0.1, 0.4)
Heterosexual men	1.0	20.7 (19.1, 22.6)	20.6 (18.8, 22.6)	0.2 (0.1, 0.6)
Women	1.0	18.1 (15.7, 21.0)	10.3 (8.5, 12.5)	0.7 (0.3, 1.7)
Adults whose sex partner had IVDA:				
Heterosexual men	1.0	15.3 (9.8, 23.9)	5.7 (2.9, 11.2)	0.7 (0.1, 9.2)
Women	1.0	21.9 (16.4, 29.2)	22.7 (16.5, 31.3)	0.3 (0.0, 4.5)
Children whose mother:				
Had IVDA	1.0	26.9 (17.0, 42.7)	16.7 (10.0, 28.0)	1.3 (0.2, 8.5)
Had sex partner with IVDA	1.0	18.7 (8.6, 40.5)	17.8 (7.8, 40.8)	0.0 (0.0, 9.7)

*Reference group: non-Hispanic Whites (99% confidence interval around relative risk is in parentheses).

TABLE 3—Relative Risk* of AIDS Associated with History of Male Homosexual Activity, by Racial/Ethnic Group and Exposure Category

Exposure Category	White*	Black	Hispanic	Other
Exclusively homosexual men:				
without IVDA†	1.0	1.3 (1.2, 1.4)	1.7 (1.6, 1.8)	0.3 (0.3, 0.4)
with IVDA	1.0	2.5 (2.2, 2.8)	2.0 (1.7, 2.3)	0.2 (0.1, 0.4)
Bisexual men:				
without IVDA	1.0	3.6 (3.3, 3.9)	2.5 (2.2, 2.8)	0.6 (0.4, 0.8)
with IVDA	1.0	4.8 (4.0, 5.7)	3.3 (2.6, 4.3)	0.1 (0.0, 0.8)
Women whose sex partner was a bisexual man	1.0	4.6 (2.9, 4.7)	3.6 (1.9, 6.9)	0.9 (0.1, 5.8)
Children whose mother's sex partner was a bisexual man	1.0	3.8 (0.9, 15.1)	1.0 (0.1, 15.4)	0.0 (0.0, 17.1)

*Reference group: non-Hispanic Whites (99% confidence interval around relative risk is in parentheses).
†History of intravenous-drug abuse.

of AIDS cases. The cumulative incidence of AIDS was correlated with the population of SMSAs ($p=0.0001$, Spearman rank sum correlation coefficient $=0.49$). The cumulative incidence was higher in Blacks and Hispanics than in Whites in each population category of SMSAs and outside SMSAs (RR range: 1.3–3.7) (Figure 1).

In the 16 SMSAs with ≥2,000,000 inhabitants, the cumulative incidence of AIDS was higher in the central cities than in the suburbs. For cases in exclusively homosexual men, in the central cities, the risk in Blacks and Hispanics was about half that in Whites; in the suburbs the risk in Blacks and Hispanics was slightly higher than the risk in Whites (Table 7). For cases associated with bisexual men, heterosexual intravenous drug abusers (IVDAs), and undetermined means of acquiring HIV infection, the risks in Blacks and Hispanics were higher than the risk in Whites in both the central cities and the suburbs. The pattern was similar in each of the four regions of the United States, except that, in the west (Los Angeles and San Francisco-Oakland), the risk of AIDS in exclusively homosexual men was lower in Blacks and Hispanics than in Whites in the suburbs as well as in the central cities.

Analysis by Time of Diagnosis

In 1980, the annual incidence of AIDS in heterosexual IVDAs was already 23.0 and 28.7 times as great in Blacks and Hispanics, respectively, as in Whites. By 1987, in Hispanics the RR of AIDS in heterosexual IVDAs had dropped to 14.8 (regression coefficient $=-0.38$, SE $=0.15$) along with a decline of Hispanics' overall RR of AIDS from 3.2 in 1981 to 2.5. The declining RR reflected an incidence increasing at a slower rate than that in Whites, rather than a decreasing incidence. The RR in Blacks has not had a significant downward or upward trend for AIDS overall or for any exposure category. In other racial/ethnic groups, the RR rose from 0.1 in 1982 to 0.4 in 1987, both overall and for cases in homosexual/bisexual men (regression coefficient $=0.018$, SE $=0.004$).

Discussion

The wide range in the RRs of AIDS in Blacks and Hispanics for different exposure categories, and the variation in these RRs by geographic area of residence, support the view that the higher risks of AIDS in Blacks and Hispanics are due primarily to behavioral and perhaps environmental differences between the racial/ethnic groups, rather than genetic differences. A large part of the difference in cumulative incidence between racial/ethnic groups may be due to different levels of prevalence of the various means of acquiring HIV infection, but reliable data on risk factor prevalence by racial/ethnic group are not currently available.

Analyses of data from drug treatment programs and emergency room visits for drug-related conditions are biased by geographical location and/or exclusion of data on private patients or drug abusers not seeking treatment.[9,16,17] Thus, the disproportionate numbers of Black and Hispanic clients in these settings provide suggestive but not conclusive evidence of a higher prevalence of IVDA in Blacks and Hispanics.

Studies of heterosexual IVDAs also have found a higher prevalence and incidence of HIV infection in Blacks and Hispanics than in Whites,[18–23] even after controlling for frequency of needle sharing.[18,20–22] This might have resulted

TABLE 4—Relative Risk* of AIDS Associated with Blood Transfusion, by Racial/Ethnic Group and Exposure Category

Exposure Category	White*	Black	Hispanic	Other
Transfusion before AIDS diagnosis:				
Men	1.0	1.2 (0.1, 1.7)	1.1 (0.7, 1.6)	0.9 (0.4, 1.7)
Women	1.0	1.9 (1.4, 2.7)	1.4 (0.8, 2.3)	1.2 (0.5, 2.9)
Children	1.0	2.5 (1.4, 4.5)	2.5 (1.2, 5.0)	0.0 (0.0, 2.4)
Heterosexual sex partner had transfusion:				
Men	1.0	24.0 (1.2, 468.0)	0.0 (0.0, 78.1)	0.0 (0.0, 194.9)
Women	1.0	0.5 (0.0, 7.6)	2.1 (0.3, 14.8)	0.0 (0.0, 14.4)
Children whose mother had transfusion	1.0	10.1 (2.1, 48.6)	4.0 (0.4, 37.4)	0.0 (0.0, 34.1)

*Reference group: non-Hispanic Whites (99% confidence interval around relative risk is in parentheses).

TABLE 5—Relative Risk* of AIDS Associated with Undetermined Means of Acquiring HIV Infection (UMAHI), by Racial/Ethnic Group and Exposure Category

Exposure Category	White*	Black	Hispanic	Other
Patients with UMAHI				
Men	1.0	7.2 (6.1, 8.5)	6.3 (5.2, 7.8)	1.2 (0.6, 2.2)
Women	1.0	12.0 (8.7, 16.6)	8.5 (5.5, 13.0)	0.7 (0.1, 4.5)
Children	1.0	7.8 (2.9, 21.0)	5.1 (1.5, 17.8)	0.0 (0.0, 12.4)
Patients with no risk factor for AIDS other than a sex partner with HIV infection but UMAHI				
Men	1.0	9.0 (3.6, 22.5)	1.9 (0.3, 12.9)	0.0 (0.0, 13.0)

Children with no risk factor for AIDS other than a mother with HIV infection but UMAHI	1.0	24.1 (6.8, 85.6)	3.2 (0.4, 27.7)	4.9 (0.3, 81.7)
Children with no risk factor for AIDS other than a mother whose sex partner had HIV infection but UMAHI	1.0	10.1 (2.1, 48.6)	10.1 (1.8, 56.5)	6.1 (0.3, 108.3)

*Reference group: non-Hispanic Whites (99% confidence interval around relative risk is in parentheses).

from greater use of "shooting galleries" by Blacks and Hispanics, where needles and syringes may be shared with a greater number of persons.*

Blacks' and Hispanics' higher cumulative incidence of AIDS associated with male homosexual activity are not easily explained, as no data are available on the prevalence of homosexuality by race/ethnicity. A study of homosexual men in San Francisco found that Blacks had a higher prevalence and incidence of HIV infection than Whites, which could not be explained by differences in number of sex partners, frequency of receptive anal/genital contact, or sharing needles for drug abuse.[24] Perhaps the higher prevalence of HIV infection in Black and Hispanic IVDAs, noted above, has led to a higher infection rate in their sex partners, whether homosexual or heterosexual.

*Personal communication: L. R. Petersen.

Blacks' and Hispanics' higher cumulative incidence of AIDS associated with male bisexuality could be due to a greater proportion of bisexuals among Black and Hispanic homosexual/bisexual men than among White homosexual/bisexual men.[25] This would be consistent with our finding of a higher risk of AIDS in Black and Hispanic women whose sex partner was a bisexual man, but is not yet significantly reflected in Black and Hispanic children whose mothers' sex partners were bisexual.

Blacks' and Hispanics' higher risk of AIDS in children who have received blood transfusions is probably due to their having a rate of low birth weight at least twice that of Whites.[26] Such births are associated with a higher rate of transfusion for treatment of iatrogenic anemia due to blood sampling in neonatal intensive care units.[27] Blacks' higher risk of AIDS in transfused women, their sex partners, and their children (Table 4) might be explained if Black women

*Cumulative incidence (CI): AIDS cases reported from June 1, 1981, to January 18, 1988, per million population.
†Reference group for relative risk (RR): non-Hispanic Whites (99% confidence interval around RR is in parentheses).
‡History of intravenous-drug abuse.

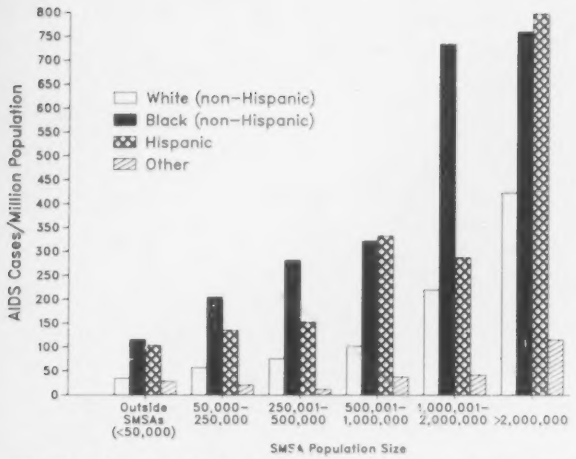

FIGURE 1—Cumulative Incidence of AIDS as of January 18, 1988 by Racial/Ethnic Group and Population Category of Standard Metropolitan Statistical Areas (SMSAs), based on the 1980 US Census

had a higher incidence of transfusions than White women. If they do, their higher transfusion rate might be due to their higher rates of birth, abortions, and ectopic pregnancies.[28–30] Alternatively, since HIV transmission by transfusion is generally only presumed in these cases, without being confirmed by assessing the HIV infection status of the blood donors, the history of blood transfusion may be merely a coincidental finding in a proportion of these cases.

Black men's lower risk of AIDS related to hemophilia suggests that this inherited disorder may be less common in Blacks than Whites, but demographic data on hemophiliacs are unavailable to substantiate this.**

Blacks' and Hispanics' higher risk of AIDS associated with undetermined means of acquiring HIV infection could result if Blacks and Hispanics were more reluctant to admit to IVDA or homosexual activity than Whites. Even without a higher rate of concealment of risk factors, however, a disproportionately high number of Black and Hispanic AIDS patients in the undetermined categories should be expected simply due to their higher proportions in the IVDA and homosexual/bisexual categories. In addition to concealing IVDA or homosexual activity in AIDS patients, these undetermined categories might reflect heterosexual transmission to persons unaware that their sex partners were IVDAs or bisexual men or had other sex partners with risk factors. Such heterosexual transmission might be occurring at a greater rate in Blacks and Hispanics than Whites.

The focus of this study has been on RRs, because they reveal differences not readily apparent from the percentage distribution of AIDS cases by race/ethnicity and exposure category. However, the importance of racial/ethnic differences in risks is reinforced by the magnitude of the proportion of Blacks and Hispanics in certain categories of AIDS patients. Of AIDS cases associated with IVDA by heterosexuals (including sex partners and children of IVDAs), more than 80 per cent were in Blacks and Hispanics. The preponderance of Blacks and Hispanics among heroin addicts was noted more than 20 years ago.[31] In addition, Blacks and Hispanics constitute a disproportionate 48 per cent of AIDS cases in women whose male sex partners were bisexual and 59 per cent of cases with undetermined means of acquiring HIV infection.

The prevalence of high-risk behavior may differ between persons in different areas, despite their belonging to the same racial/ethnic group as broadly categorized here. For example, if high-risk homosexual activity were more prevalent in Whites or less prevalent in Hispanics in the western US than in their counterparts in other regions, either situation could explain why the RR in Hispanics is lower in the west than in other regions (Table 6). The same principle could explain why, in the central cities, the general populations of Blacks and Hispanics have a lower cumulative incidence than Whites of AIDS in exclusively homosexual men (Table 7). Since our comparison of central cities with suburbs was limited to SMSAs with ≥2,000,000 population, the differences observed may not necessarily reflect the situation in smaller SMSAs or outside SMSAs. Independent of the prevalence of high-risk behavior, the prevalence of HIV infection may differ between regions due to differences in the time when the epidemic began in particular exposure categories.

Our analysis of trends was too early to assess the impact of the 1987 revision of the AIDS case definition on relative risks, as reporting of cases under the revised definition did not begin until September 1, 1987.[10]

The possibility that the observed higher risks in Blacks and Hispanics may be due to biased data needs to be considered. The proportion of the population not counted in the 1980 census was greater for Blacks†[32] and Hispanics‡ than Whites. When we modified our calculations, however, by increasing the populations by estimates of their undercounts, RRs in Blacks and Hispanics were not significantly reduced. If private physicians were more concerned than other physicians about guarding the confidentiality of their patients, reporting of AIDS cases might be more complete in indigent (disproportionately Black and Hispanic) patients of public hospitals than in patients who can afford private medical care. A bias in the opposite direction, however, may result if indigent patients were less likely to undergo expensive diagnostic procedures needed to meet the AIDS case definition (presumptive diagnoses were not accepted until September 1987).[10] A reporting bias would probably be too small to explain the magnitude of the observed RRs, since a validation study estimated the completeness of AIDS reporting to be about 90 per cent, a rate that did not vary by racial/ethnic group.[33] Furthermore, a reporting bias would be unlikely to explain fully the variation in RRs by exposure category and geographic area.

HIV-antibody tests in applicants for military service[34] and in volunteer blood donors[35] have shown that the prevalence of HIV infection is higher in Blacks and Hispanics than in Whites, but not higher in American Indians/Alaskan Natives and Asians/Pacific islanders. This supports our analyses. Awareness that the risk of AIDS is not higher in racial/ethnic minorities other than Blacks and Hispanics

should help stop misleading generalizations that imply higher risks in all "minority" groups.[2,3,18]

Black and Hispanic communities should be targetted for special efforts to prevent and treat IVDA and to counsel IVDAs on the risk of HIV infection. The need for this is greatest in the northeast. Recommendations for preventing HIV transmission to IVDAs, their sex partners, and their children have been published.[36-41] Black and Hispanic women need to know that they can acquire HIV infection by sexual contact with male IVDAs. Prevention messages to Black and Hispanic men must be addressed not only to men who identify themselves as gay, but also to men who see themselves as basically heterosexual despite occasional sexual relations with other men. For these and other recommendations to be implemented, they must be endorsed by Black and Hispanic community leaders and others whose judgment is respected by the persons for whom the messages are intended.

New Quarterly *Journal of Human Lactation* Announced

A new quarterly journal—the *Journal of Human Lactation*—has been launched by the International Lactation Consultant Association (ILCA) to provide current information on the latest clinical concerns relating to human lactation and breastfeeding. Features include research and scientific articles, commentaries focusing on controversial issues, and brief reports highlighting the clinical application of new knowledge about lactation and the breastfeeding encounter. In addition, *JHL* includes listings of relevant articles from other sources, offers discussions of practice-oriented concerns of lactation consultants in a variety of settings, and news of political/governmental/marketing activities that influence breastfeeding women worldwide.

Kathleen G. Auerbach, PhD, is Editor-in-Chief of *JHL*. The editorial offices are located at 2240 Willow Road, Homewood, IL 60430-3221. Subscriptions ($40 individual; $50 institutions) are handled by ILCA, Department PH, PO Box 4031, University of Virginia Station, Charlottesville, VA 22903 USA.

Prevalence of Cardiovascular Disease Risk Factors in Blacks and Whites: The Minnesota Heart Survey

J. Michael Sprafka, PhD, Aaron R. Folsom, MD, Gregory L. Burke, MD, and Stanley A. Edlavitch, PhD

Abstract: Two cross-sectional surveys were conducted in 1985 and 1986 to measure the prevalence of coronary heart disease (CHD) risk factors in Blacks and Whites. A home interview was followed by a survey center visit. Participation rates were 78 per cent and 90 per cent for the home interview and 65 per cent and 68 per cent for the survey center visit. Adjusted for age and education, systolic and diastolic blood pressure was 3 to 4 mmHg higher in Blacks. Hypertension was more prevalent in Blacks than Whites (44 per cent vs 28 per cent); serum total cholesterol was approximately 0.4 mmol/l lower in Black than White men and 0.08 mmol/l lower in Black than White women. Among men, more Blacks than Whites were current cigarette smokers (44 per cent vs 30 per cent); however, White smokers smoked more cigarettes per day (26 vs 17). Similar differences were noted for women, although the prevalence and quantity of cigarette consumption was less than men. The excess prevalence of these CHD risk factors in Blacks, especially among women, may explain their elevated CHD and stroke mortality rates in the Twin Cities. (*Am J Public Health* 1988; 78:1546–1549.)

Introduction

The relation of blood pressure, serum cholesterol, and smoking to coronary heart disease (CHD) incidence and mortality rates has been reported in many epidemiologic studies both nationally and internationally.[1–3] CHD mortality rates are higher for Blacks than Whites at younger ages, and lower for Blacks after the age of 70.[4–6] Whether racial differences reflect access to medical care or prevalence of CHD risk factors is unclear. Few reports compare the prevalence of the known CHD risk factors between Blacks and Whites. This paper describes the prevalence of coronary heart disease risk factors in Blacks and Whites using data from two population-based surveys in a large metropolitan area.

Methods

Study Population

Methods and early findings from the Minnesota Heart Survey, a survey of CHD risk factors and related behaviors in probability samples of Twin Cities residents aged 25 to 74 years, have been described previously.[7] The seven-county metropolitan area was divided into 704 clusters of approximately 1,000 households each, based on 1970 and 1980 census information, from which 40 clusters and approximately 10 per cent of households within each cluster were randomly selected. One individual aged 25–74 was randomly selected per household, interviewed in the home, and then invited to attend a neighborhood clinic for more extensive interviews and physiologic tests. The first series of general population surveys was conducted in 1980–82. A second series was begun in December 1985, with two complete one-year survey cycles.

From July to November 1985, we also surveyed an area of Minneapolis with large numbers of Black residents to provide more precise estimates of their CHD risk factors. In the sampling area, which included four and one-half census tracts, every occupied housing unit was identified and *all* 35- to 74-year-old Blacks were considered eligible and recruited to the survey. Other methods were identical to those in the general population survey; preliminary findings are detailed elsewhere.[8,9]

Data on Risk Factors

In both surveys, height was measured in stocking feet to the nearest half inch. Body mass index (BMI) was computed as $wt/ht^2 (kg/m^2)$. Blood pressure was measured by trained technicians using a random zero sphygmomanometer on the right arm of seated participants after a five-minute rest. The average of two measures of systolic and diastolic (5th phase) is reported. Non-fasting blood specimens were obtained using the protocol of the Lipid Research Clinics.[10] The Jenkins Activity Survey[11] was used to assess Type A behavior (positive scores indicate more Type A tendencies and negative scores more Type B). The Minnesota Leisure Time Physical Activity (LTPA) questionnaire[12] was administered to a systematic 50 per cent sample of study participants. The systematic 50 per cent not receiving the LTPA were given a 24-hour dietary recall questionnaire. Exertional anginal pectoris,[13] smoking, alcohol use, demographics, and medication use were assessed by questionnaire.

Analysis

Data on Whites aged 35 to 74 from the first cycle of the 1985–87 general population survey were compared to those obtained from the 1985 Black population survey. We used analysis of variance to adjust for the effects of age and education to determine the relationship and overall significance of racial differences.[14]

Results

Participation rates in the general population survey were 90 per cent for the home interview alone and 68 per cent for the home interview and clinic visit. Participation rates in the 1985 Black survey were 75 per cent and 65 per cent, respectively. In both surveys individuals attending clinic were more likely than non-clinic attenders to be non-smokers (47.7 per cent vs 63.2 per cent), have more education (greater than high school education, 54.0 per cent vs 48.1 per cent), be married (63.8 per cent vs 57.9 per cent) and be currently employed (71.1 per cent vs 66.3 per cent). No differences were noted in the percentages of individuals with a history of high blood pressure, hypercholesterolemia, diabetes, heart attack, or stroke or in leisure time physical activity scores between clinic attenders and non-attenders. Table 1 shows

†For income status N = 763–WM; 457–BM; 811–WW; 590–BW.

the sociodemographic characteristics of men and women by race adjusted for age.

The age-adjusted prevalence of diabetes, angina, history of heart attack or stroke, and average body mass index was higher in Black than White women (Table 2). No racial difference in these conditions was noted for men. In general, scores for physical activity and Type A behavior were higher in Whites than Blacks. Alcohol consumption was higher in Black than White men with no differences noted for women.

For all age groups, systolic and diastolic blood pressures were higher in Blacks than Whites by 3 or 4 mmHg (Table 3). These differences remained after stratification by antihypertensive medication status. The prevalence of hypertension, defined as systolic blood pressure greater than or equal to 140 mmHg and/or diastolic blood pressure greater than or equal to 90 mmHg and/or currently taking antihypertensive medication, was higher in Blacks than Whites for all age-sex categories (Table 4).

Figure 1 shows that a greater percentage of Black than White men were aware of their hypertension, treated and controlled. More Black than White men had treated but uncontrolled hypertension, except 65- to 74-year-olds. The percentage of men aware of their hypertension yet untreated and uncontrolled was similar in Blacks and Whites and decreased consistently with age. Overall, the percentage of men unaware of their hypertension was markedly higher among Whites than Blacks (38 per cent vs 27 per cent: mean difference = 10.5 per cent, 95 per cent CI = 1.7, 19.3).

Compared to men, women were more aware of their hypertension (Figure 2) and it was better treated and con-

trolled in all ages. The fraction of women diagnosed, treated and uncontrolled averaged approximately 25 per cent in both Blacks and Whites. More White than Black women were unaware of their hypertension (24 per cent vs 15 per cent: mean difference = 8.9 per cent, 95 per cent CI = 1.7, 16.1).

In general, Black men had lower serum total cholesterol and higher serum HDL cholesterol levels than White men

*1 mg/dl = 0.02586 mmol/l.

(Table 5). Black women had slightly lower serum total cholesterol values than Whites among individuals aged 35 to 54 and the differences increased with age. Black women had slightly higher values of serum HDL cholesterol than White women in the younger age groups and this difference increased with age. The ratio of HDL to total serum cholesterol remained relatively stable with age in men but gradually declined in women.

The age- and education-adjusted prevalence of cigarette smoking was higher in Black than White men (43.9 per cent vs 29.5 per cent) and women (27.9 per cent vs 17.9 per cent).* Black and White men were equally likely ever to have smoked, but many more of the White men had quit. More Black than White women were current cigarette smokers especially among those aged 35 to 44. Black women were more likely never to have smoked than White women, but fewer Black women had quit.

Discussion

The effect of non-response on the CHD profiles in this study is unknown; however, previous reports indicate that survey non-participants more often are unmarried, unemployed, smokers, and have alcohol problems than participants.[7,15] Our findings on clinic participation are consistent with these observations. Overall response rates were similar in the Black and general population surveys, 65 per cent and 68 per cent, respectively.

With the exception of serum total and HDL cholesterol levels and Jenkins Activity Survey scores,[11] Blacks had a relative excess of the known CHD risk factors. The results regarding blood pressure, blood lipids, and cigarette consumption differences between Blacks and Whites agree closely with those reported elsewhere.[16–19] If, as our data suggest, these blood pressure differences between Blacks and Whites are not attributable to lower hypertension awareness and treatment patterns among Blacks, one possible explanation is that Blacks have more severe hypertension with earlier

*Data available on request to author

onset and poorer control when treated. Differences between Blacks and Whites in hypertension awareness and control in this survey are consistent with the National Health and Nutrition Examination Survey (NHANES) data[20]; but the percentages of individuals aware, treated and controlled are much higher than those reported in NHANES for both men and women, Black and White, suggesting that Minnesota may have more effective hypertension control programs than the US as a whole.

Average serum cholesterol levels among US adults have declined significantly in the last 20 years for Whites but not for Blacks.[21] The average serum cholesterol level in Blacks is lower than in Whites in Minnesota and nationwide, yet Blacks in this study had higher serum HDL cholesterol values than Whites. Reasons for this are unclear and are not likely explained by differences in alcohol and cigarette consumption, obesity, or physical activity. A genetic component, as suggested by Gartside, *et al*,[23] might be an hypothesis needing further exploration.

The excess of CHD risk factors among Twin Cities Blacks, especially women, may partially explain their elevated cardiovascular mortality rates.[8] Despite significant declines during the last decade for all sex- and race-specific groups, heart disease mortality rates are higher in Blacks than Whites (10 per cent excess in men, 60 per cent excess in women). In addition, stroke mortality rates are higher in Blacks than Whites (23 per cent excess in men; 79 per cent excess in women). Public health interventions must focus on reducing these risk factors if further improvements in Black CHD mortality rates are to be seen.

Behavioral Aspects of Cigarette Smoking among Industrial College Men of Shanghai, China

VIRGINIA C. LI, PHD, HU JIN-HUA, ZHOU MANLAN, AND ZHENG JIABAO

Abstract: A questionnaire survey was conducted among 7,665 students and staff in the factory-operated industrial colleges in Shanghai, China. Response rate was 95.7 per cent. The proportion of smokers among the men was 50.5 per cent; only 0.33 per cent of the women reported they were smokers. Male smokers began smoking upon entering the work force, where social interaction encourages cigarette smoking. Seventy per cent of the male smokers smoked fewer than 10 cigarettes per day. Only 4.3 per cent perceived themselves as very addicted; 3.4 per cent reported they had no confidence in their ability to control the amount they smoke. The Chinese smokers are more likely to succeed in giving up cigarette smoking for at least one day, as well as for longer periods, compared to US smokers. The number of cigarettes smoked may be related to the individual's purchasing power. For China, strategic timeliness in legislative action and education is urgently needed to combat the high prevalence of cigarette smoking in males, at extremely high risk. (*Am J Public Health* 1988; 78:1550–1552.)

Introduction

China leads the world in tobacco production. Cigarette manufacturing and sales are state monopolies; annual profit to the state from the tobacco industry constitutes 8 per cent of national income and is one of the largest sources of revenues for the Chinese government.[1] In 1987, of the 50 largest industrial enterprises in China, eight were manufacturers of tobacco products.[2]

There are indications that lung cancer and ischemic heart diseases are on the rise in China.[3,4] In recent years, China's State Patriotic Health Campaign Commission has assumed an advocacy role in smoking prevention.[5] Since the Commission is an arm of the State Council, the highest executive body of the central government, this suggests that the State recognizes the health consequences of smoking. Efforts to call public attention to the health risks of smoking are increasing.[6]

The World Health Organization-Shanghai Collaborating Center for Health Education was established in 1985 to strengthen health education and the delivery of primary care to local communities. The Center supported a systematic survey to determine smoking prevalence, knowledge, attitudes, and behavioral characteristics of the students and staff of factory-operated industrial colleges in the municipality of Shanghai. This paper reports the survey findings.

Methods

Study Population

Twenty-six of the 54 factory-operated industrial colleges in Shanghai participated in the study, with a total of 7,665 students and staff. The industrial colleges are three-year technical schools offering specialization in various occupations. They have from 107 to 671 students, and a student/staff ratio of 2:1. The students are older than general university students. They have had at least one year of practical work experience.

Procedures

A self-administered structured questionnaire was designed to determine demographic characteristics, cigarette smoking knowledge, attitudes and behavior, and reasons for cigarette smoking, and smoking and quitting. The survey was implemented in January 1986.

Cooperation from the project sites was obtained by the Center staff. The clinic physician or health worker was usually assigned as the site coordinator at each of the participating colleges. Coordinators were trained by the investigators to administer the questionnaire in group settings. When respondents were illiterate (less than 0.3 per cent), coordinators helped them complete the questionnaire.

Results

Of the 7,339 respondents (95.7 per cent of those eligible), 4,899 were men and 2,440 women. The mean age was 30.8 ± 9.7 years for men and 28.7 ± 7.7 years for women.

Chinese smokers are almost exclusively male. The proportion of current smokers among the men was 50.05 per cent (N = 2,447), while only 0.33 per cent (N = 9) of the women reported that they smoked. Among the men, 90 per cent of the non-smokers versus 84 per cent of the smokers had some college level education; marital status of smokers and non-smokers did not differ appreciably. Nearly 90 per cent of the respondents reported they were very satisfied with their work, irrespective of smoking status. Since there were so few female smokers, the remainder of this analysis will focus on the male smokers.

Smoking Behavior

The bulk of the smoking men were light smokers (Figure 1). Of the smokers who reported the amount they smoked (88 per cent), 70 per cent reported that they smoked an average of one to 10 cigarettes per day, and less than 5 per cent smoked one or more packs per day. Smokers used both filter and non-filter cigarettes; 16 per cent of respondents said that they did not inhale, 28 per cent lightly inhaled, 48 per cent usually inhaled, and 8 per cent deeply inhaled.

The onset of cigarette smoking occurred in early adulthood when the individual entered the job market and began to earn an income. Twenty-five per cent of the male smokers started smoking cigarettes between the ages 15–19, 55 per cent between ages 20–24.

Figure 2 shows that older smokers tended to smoke more cigarettes than the younger smokers. The proportion doubled

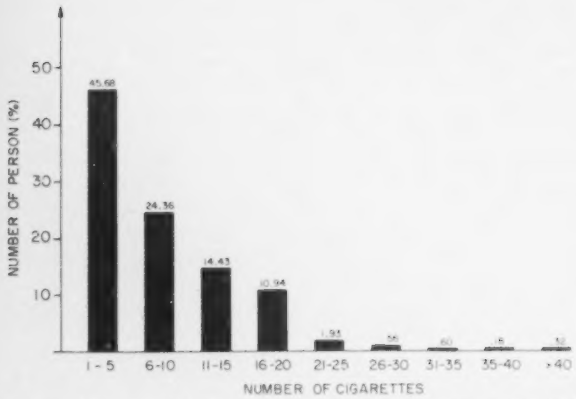

FIGURE 1—Average Number of Cigarettes Smoked among Men in Shanghai Industrial Colleges, 1986

for 11–20 cigarettes, quadrupled for 21–30 cigarettes, and increased ten-fold for 31–40 cigarettes.

Nearly all (96 per cent) of the male smokers were able to identify where they smoked the first cigarette of the day: the workplace (34 per cent), with friends (32 per cent), at home (14.4 per cent), and at school (12.8 per cent). The social aspect of cigarette smoking is even more evident when "friends" are combined with "home of relatives and friends" (35.8 per cent). Only 6 per cent of smokers reported no smokers among their five closest associates, compared to 16.3 per cent of the non-smoking respondents. The male smokers also reported that 63 per cent of their superiors smoked compared to 48 per cent of the non-smoking respondents. With respect to family members who smoke, the proportions of fathers (46.8 per cent), brothers (35.6 per cent), and children (6.1 per cent) of smokers were all higher compared to fathers (39.9 per cent), brothers (24.1 per cent), and children (2.9 per cent) of non-smokers.

Table 1 presents the reasons smokers gave for smoking (93 per cent reported at least one reason). The most common reasons given for smoking were social need (78.7 per cent), problems with work/study (61.3 per cent), and relaxation (54.1 per cent). A relatively low percentage of respondents reported "pleasure" (27.6 per cent) and "desire for cigarettes" (11 per cent). When smokers were asked about their

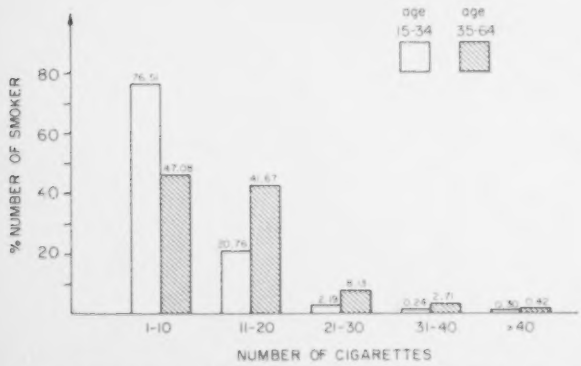

FIGURE 2—Average Number of Cigarettes Smoked per Day by Age, among Men in Shanghai Industrial Colleges, 1986

TABLE 1—Reasons for Smoking and Per Cent Respondents among Men in Industrial Colleges, Shanghai, 1986

Reasons for Smoking	% Respondents	% Respondents Giving Positive Responses
	N = 2,447	
Social needs	80.9*	78.7
Problems with work/study	71.8	61.3
Relaxation	70.4	54.1
Stress Reduction	68.9	51.5
Problems at home	66.8	42.4

Desire for cigarettes	62.9	11.0

*Response related to higher educational level for all reasons by χ^2, $p < .005$.

desire to smoke in places where smoking is not appropriate, 96 per cent responded: 65 per cent reported no desire, 31 per cent some desire, and 4 per cent great desire.

Health Knowledge about Cigarette Smoking

Table 2 shows that the majority of both non-smokers and smokers were aware that cigarette smoking may cause cancer and heart disease, and be harmful to the fetus, but more non-smokers than smokers were aware of all these risks.

Over 75 per cent of the non-smokers compared to 37 per cent of the smokers acknowledged that smoking is a distasteful habit. Only about 50 per cent of the respondents, both smokers and non-smokers, felt that cigarette smoking is an addictive habit.

Teachers were consistently more knowledgeable than the other respondents about the hazards of cigarette smoking.

Smoking Cessation

Smokers were asked whether they had been advised by someone to stop cigarette smoking. Of the 93 per cent who responded, 65 per cent had received such advice during the previous year; 98 per cent gave information on whether they had made a serious attempt to quit following the advice, and 39 per cent reported having tried to quit. Figure 3 shows that of those who tried about half were able to quit for six weeks and almost one-third had quit for up to five months before relapsing. In their previous attempts to quit cigarette smoking, 74 per cent said that they did not feel any adverse sensations when quitting, but 26 per cent did experience nervousness and anxiety.

Smokers were queried about the reasons for wanting and not wanting to quit smoking. Fifty-two per cent gave at least one reason for quitting, with "improve health" (66 per cent) being the leading reason. Other reasons were: "too expensive" (44.6 per cent), "bad for health," (42.4 per cent), "not

TABLE 2—Health Hazard Knowledge of Cigarette Smoking among Men in Industrial Colleges, Shanghai, 1986

Health Hazards	Smokers N = 2,262	Non-Smokers N = 5,623
Cigarettes may cause cancer	70.3	86.5
Cigarettes may cause heart disease	55.1	62.3
Passive smoking is harmful to unborn child	75.6	87.8
Passive smoking is harmful to health	72.5	87.5

want to smoke" (36 per cent), "bad habit" (37.7 per cent), "advised to quit" (31.8 per cent), and "bad example" (17.5 per cent).

As to specific methods of quitting smoking, "using will power" was cited by 74 per cent of the respondents. Other methods included "substitution by food and drinks," "reminder by family and friends," "forming a quit smoking group," and "self-monitoring." However, the proportions who reported having used these methods were small, ranging from 18.6 per cent to 9.7 per cent.

Consistent with the data on the number of cigarettes smoked per day, only 4.3 per cent of the smokers perceived that they are very addicted, and 3.4 per cent reported that they have no confidence in their ability to control the amount of cigarettes they smoke. The proportion who felt that they were totally in control of the amount of cigarettes they smoked (56.4 per cent) was greater than those who indicated they were not addicted (45.3 per cent). This suggests that many who consider themselves somewhat addicted are also confident that they are in control of their smoking habits. Eight per cent of the smokers predicted that they would be ex-smokers one year from the time of the study. Nearly all smokers (97 per cent) responded to the question on their desire to smoke in places where smoking is not appropriate. Significantly, 65 per cent said "no", 31 per cent said "sometimes", and 4 per cent said "frequently".

Discussion

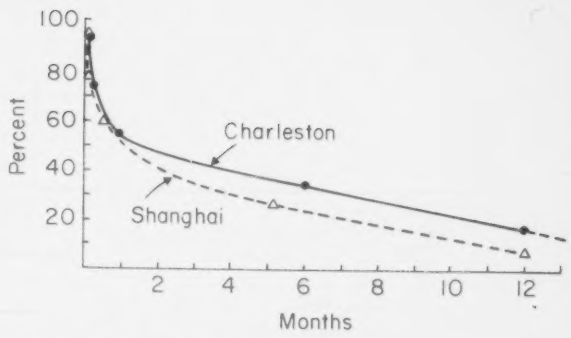
The proportion of smokers reported in the Shanghai industrial colleges is lower than that reported for the general Chinese population,[5] perhaps because of the higher education levels of the Shanghai sample.

The Shanghai data revealed the enormous discrepancy in smoking rates between men and women in China. Why, in a society that is ideologically egalitarian, is there such a marked discrepancy between the sexes in smoking rates, when these rates are increasingly becoming equal between the sexes in western countries?

The strongest influence on women smoking in the west has been commercial advertising. Beginning in the 1920s, tobacco companies in the west have systematically targeted women, capitalizing on their growing income and sense of independence.[9,10] After World War II, women constituted one of the fastest growing segments of the tobacco market.[11] Commercial advertising is restricted and women are largely untouched by commercial exploitation in socialist China. But even in pre-revolutionary China, female cigarette smoking was frowned upon, often associated with prostitutes, and thus traditionally unacceptable.

In western countries those who have not adopted the smoking habit by age 20 are unlikely ever to do so. In Shanghai, however, only 25 per cent of adult smokers had started to smoke before age 20 and none reported having smoked before age 15. There is a strict policy to expel any students from high schools for smoking cigarettes. Also, Chinese children seldom receive a money allowance from their parents and it is rare for young teenagers to earn pocket money, as jobs are assigned and controlled by the state or community. Thus, young people are not likely to have the money to buy cigarettes until they become wage earners.

The Chinese smoke fewer cigarettes compared to westerners. A limiting factor which has kept tobacco consumption low in China compared to other countries is the cost of cigarettes relative to income. Chinese domestic low grade



Source: Li et al, 1983

FIGURE 3—Per Cent of Shanghai Males Abstaining from Smoking by Duration of Longest Previously Reported Abstinence, Compared to Charleston Shipyard Workers

cigarettes cost thirty cents per pack, and better grades cost almost one yuan* per pack. The salary of Chinese wage earners averages about one hundred yuan per month in cities, and less in rural areas. Since about one-half of the salary goes for food, even one yuan adds up to a significant portion of the money available. The rising standard of living could lead to a rapid increase in cigarette consumption. Moreover, an increase in consumption could result in many social smokers becoming addicted.

Based on the limited data from Shanghai and a study of 848 male smokers in the Charleston naval shipyard conducted by Li and associates,[12] it appears that western smokers, possibly due to heavier consumption, have a harder time quitting smoking compared to Chinese smokers. The parallel curves in Figure 3, comparing the American smokers to the Chinese male smokers, suggest that in their attempts to quit, Chinese smokers are more likely than Americans surveyed to succeed in giving up cigarette smoking for at least one day (96 per cent vs 93 per cent), as well as for one year or longer (19 per cent vs 11 per cent), before relapse.

The main reason the Chinese smoke is social. Hosts offer cigarettes to guests as a sign of hospitality and sincere friendship. People light up as a gesture in accepting the hospitality and friendship. Government education to reduce smoking must focus on social needs of the people. It must promote role models for refusing cigarettes and create an environment in which smoking is seen as an anti-social behavior.

Paradoxically, because China is a planned society, the government is in a position to outlaw the production and sale of cigarettes, if there is political will to replace the revenue lost in banning tobacco production and manufacturing. Arguments for strategies for smoking control and long range planning for the diversion and substitution of tobacco crop have appeared in the *People's Daily*,[6] an official organ of the state and the most influential newspaper in China. Recently, Beijing took the major step of declaring 100 public places in the city smoke free, including hospitals, public transportation, and sports arenas.[13] Beijing's action in anti-smoking legislation could serve as a role model for the rest of the country.

* The exchange rate for Chinese currency (yuan) to the US dollar is approximately 1:3.7.

ACKNOWLEDGMENTS

We wish to thank the World Health Organization Western Pacific Region for the partial support of the study, and the industrial colleges in Shanghai for their cooperation. Special thanks is due to Huang Wai Hua for her assistance in data analysis, William McCarthy for his comments, and Robin Zenger for editorial assistance.

Advocacy Institute Issues Summary on Effects of Cigarette Smoking and Radon Exposure

The Washington-based Advocacy Institute, through its Smoking Control Advocacy Resource Center (SCARC), issued an "action-alert" news release in mid-October summarizing the effects of cigarette smoking on radon exposure and encouraging tobacco control advocates to seize the opportunity to "increase the public's perception of tobacco as an agent of disease that multiplies the hazards of radon and other environmental hazards." The message of the news release-summary is excerpted and paraphrased below:

On September 12, 1988, the US Environmental Protection Agency (EPA) issued a national health advisory concerning the effects of radon exposure. Radon, an invisible and odorless gas that is formed when uranium in soil and rocks decays, can produce high levels of radioactivity. According to EPA, the toxic action level occurs when the level of radon reaches 4 pci (picocuries) per liter of air—an amount equivalent to smoking half a pack of cigarettes a day.

EPA has estimated that eight million homes in the US may have potentially hazardous radon levels. Cigarette smoking, particularly in a radon-exposed house, would therefore pose a significant health threat to smokers and nonsmokers alike. In addition, EPA has stated:

- The cancer risk of smoking more than a pack of cigarettes a day is equivalent to spending 75% of the time in a house with a radon level that exceeds the health protection standards.
- Of the 20,000 deaths per year from radon-related lung cancer, 15,000 (75%) are smokers. Of the 140,000 total lung cancer deaths in America each year, smoking is responsible for 119,000.
- The risks for smokers exposed to radon is 15 times greater than for nonsmokers.
- Tobacco smoke acts as a carrier which draws radon particles from the air deep into the lungs. Therefore, smoking in a radon-exposed house increases the chances of radon-induced lung cancer for all persons in contact with the smoke.

According to William Mills, former Radiation Division Chief at EPA, "The message is, if you want to decrease your risk from radon, stop smoking; it's that simple."

The Advocacy Institute suggests that "Tobacco control advocates need to seize this occasion to convert the issue from a radon dilemma to a smoking problem." Some of the methods they suggest for accomplishing this include:

- Contact local radon testing programs to urge that they include surveying for smokers in the households they test. Ask that their inspectors stress "no smoking" as one easy and immediate corrective action.
- Contact local health reporters to emphasize tobacco as the agent of disease which multiplies the hazards of radon.

Fractures and Lifestyle: Effect of Cigarette Smoking, Alcohol Intake, and Relative Weight on the Risk of Hip and Forearm Fractures in Middle-Aged Women

David Hemenway, PhD, Graham A. Colditz, MB, BS, Walter C. Willett, MD, Meir J. Stampfer, MD, and Frank E. Speizer, MD

Abstract: Cigarette smoking, alcohol consumption and low relative weight are often cited as risk factors for osteoporosis. In a prospective cohort study of 96,508 middle-aged nurses 35 to 59 years of age we found that smoking was not a risk factor for hip and forearm fracture. Women who drank more than 15 grams of alcohol per day and whose relative weight was less than 21 kg/m^2 were at increased risk of fractures, but these risk factors were not independent. Only the combination of alcohol intake and thinness substantially increased the likelihood of fracture. The low weight women consuming more than one drink per day comprised but 4 per cent of our population of middle-class women and sustained 6 per cent of the fractures. (*Am J Public Health* 1988; 78:1554–1558.)

Introduction

As with many other medical problems, osteoporosis has been associated with various lifestyle variables such as cigarette smoking,[1–4] high alcohol consumption,[4–6] and relative weight.[1,4,7] The relation between fractures and smoking and drinking has not been clearly documented,[8–12] but the association between fractures and relative weight is clear: a retrospective cohort study[13] and various case-control studies[8–10,14] have consistently shown that thin women are more likely to suffer hip and forearm fractures than their more obese counterparts.

We employed a prospective approach to investigate risk factors for fracture. With data from the Nurses' Health Study, a large prospective cohort study of middle-aged women with nursing training, we estimated the effect of cigarettes, alcohol, and obesity on the risk of fractures of the hip and forearm.

Methods

In 1976, 121,700 female registered nurses, ages 30 to 55, living in 11 large US states, completed a mailed questionnaire on known and suspected risk factors for cancer[15] and coronary heart disease.[16] Based on a subsample of the cohort, we estimate that at least 98 per cent are White. Every two years, a follow-up questionnaire has been sent to update and add to the information about these women and to record the occurrence of cancer, heart disease, and other major health problems.

In 1980, 103,000 women responded. From these we excluded women with a history of cancer (other than non-melanoma skin cancer) and the 4 per cent of women who did not answer either the 1982 or 1984 questionnaire leaving a total of 96,508 nurses. We used information on age, weight, height, smoking, and alcohol from the 1980 questionnaire. In 1982 and 1984, we asked participants whether they had sustained a fracture to the hip or forearm in the previous two years. Women responding yes on either questionnaire were considered cases if their fracture occurred after the return of the 1980 questionnaire and before June 1, 1984. To assess the validity of this self-report, we asked a random sample of 50 women who reported fractures on the 1982 questionnaire for permission to review the relevant medical records. Forty-three women responded and confirmed their prior self-report, and 33 gave us permission to review the records. All medical records obtained confirmed the self-report.[17]

Cumulative incidence rates were determined for fractures occurring during the four years of follow-up (1980–84). Relative risks (cumulative rate ratios) were calculated as a measure of association. Using the self-reported age on the 1980 questionnaire, we divided the women into five age categories of roughly equal size: ages 35–39 (22 per cent of the women); 40–44 (20 per cent); 45–49 (21 per cent); 50–54 (20 per cent); 55–60 (17 per cent). Respondents were also divided into five smoking categories: never smoked (44 per cent); ex-smoker (27 per cent); one to 14 cigarettes per day (8 per cent); 15 to 24 cigarettes (12 per cent); more than 25 (8 per cent). Less than 2 per cent of the women failed to respond to this question.

We estimated the number of grams of alcohol intake per day. Respondents were asked about their average use in the past year of beer (bottles or cans), wine (glasses), and liquor, i.e., whiskey, gin, etc. (drinks). They were instructed to select one of nine categories for each type of alcohol: 6+ per day; 4-6 per day; 2–3 per day; 1 per day; 5–6 per week; 2–4 per week; 1 per week; 1–3 per month; almost never. The alcohol content was estimated to be 13.2 grams for a bottle or can of beer, 10.8 grams for a glass of wine, and 15.1 grams for a drink of liquor. Total alcohol intake for each individual was computed as the sum of the contribution from beer, wine, and liquor. We divided the women into five groups: total alcohol intake per day = 0 (30 per cent); between 0 and 1.4 grams/day (12 per cent); from 1.5 to 4.9 grams/day (20 per cent); from 5 to 15 grams (19 per cent); and greater than 15 grams (13 per cent). (Five grams per day is the equivalent of about three drinks per week). Seven per cent of the women did not provide plausible responses to the diet component of the 1980 questionnaire, and thus were not categorized for alcohol intake. Alcohol intake responses have been validated as part of the overall validation of the Nurses' Health Study food frequency questionnaire.[18,22] Questionnaire data were highly correlated with alcohol intake recorded during four one-week diet periods ($r = 0.90$), and were reproducible over one year ($r = 0.90$).

Relative weight was calculated as weight in kilograms

TABLE 1—Hip and Forearm Fractures 1980–84 (4 years) by Age

	Age (years)				
Age in 1980	30–35	40–44	45–49	50–54	55–60
No. of Cases	94	84	155	301	291
No. of Women	21,334	19,501	20,118	19,429	16,126
Incidence (cases/10,000 person-years)	11.0	10.8	19.3	38.7	45.1

divided by height in meters squared (Quetelet's index) and categorized as: less than 21 kg/m^2 (21 per cent of the women); 21 to 23 (24 per cent); 23 to 25 (20 per cent); 25 to 29 (20 per cent) over 29 (14 per cent). Six per cent of the women did not provide sufficient information and were not categorized. A relative weight of under 21 kg/m^2 corresponds to a 5'4" woman weighing less than 122 pounds. A relative weight of more than 29 kg/m^2 corresponds to a 5'4" woman weighing more than 169 pounds.

Weight data for the nurses also have been collected as part of a validation study which showed that self-reported weight was highly correlated with measured weight (r = 0.96).[15]

Results

Slightly under 1 per cent of the respondents (925 of 96,508) reported a fracture to the hip or forearm in the period from the date of return of the 1980 questionnaire to June 1, 1984.

Like other observers, we found a strong increase in fracture rates with increasing age (Table 1). Women in the 55–60 age group had over four times the likelihood of experiencing a fracture in the succeeding four years compared to women ages 35–44.

We observed no relation between smoking categories and likelihood of fracture either overall or within any five-year age category (Table 2). There was some suggestion of an association between alcohol consumption and fractures (Table 3). Among women consuming 15 or more grams of alcohol per day, compared to abstainers and light drinkers, the relative risk was 1.24 (95 per cent confidence interval 1.04, 1.48) (Table 3).

Compared to those of higher relative weights, the thinnest women (<21 kg/m^2) were at increased risk for fracture. (Table 4). For women with relative weights above 21 kg/m^2, the age-adjusted risk of fractures did not vary by weight. The increased risk observed for lean women was limited to women over 50 years of age.

We analyzed the interrelation between thinness and alcohol intake characteristics (Table 5). Women who drank more than 15 grams of alcohol per day were not at increased risk unless they were thin, and women who were thin were not at increased risk unless they drank more than 15 grams of alcohol per day. The low weight women who drank most heavily had an age-adjusted risk of fracture 70 per cent above the rest of the women in the study (relative risk = 1.73, 95 per cent CI = 1.30, 2.29). In terms of absolute risk, the low weight-heavier drinkers accounted for under 4 per cent of the study population and reported 6 per cent of the fractures. We observed no interaction between relative weight, cigarette smoking, and risk of fractures in this population.

Discussion

A recent consensus conference argued for additional "observational and epidemiologic studies to determine the impact of multiple and behavioral factors on . . . fracture frequency. Such studies could be conducted by appropriate additions to existing population-based studies."[19] In accord with that recommendation, we examined the relationship between the risk of hip and forearm fracture and three lifestyle characteristics: cigarette smoking, alcohol consumption, and relative weight. The study was large—prospective data were collected on close to 100,000 nurses—so any substantial relationship would be detectable. However, the fact that the women in the study were middle-aged (no one was over 65 in 1980) may limit the generalizability of the results.

While the data are based on recall, the presumption that these trained nurses are reliable reporters has been corroborated by various validity checks.[15,17,18,20] In addition, the questionnaire data have been used to corroborate associations reported from other epidemiologic studies of risk factors for heart disease and cancer.[15,16,21–23]

We observed a marked increase in fracture rates with age. The absolute rates reported are probably slight under-

TABLE 2—Incidence of Fractures, by Age, Smoking (cases/10,000 person-years)

estimates of the real rates. A few respondents may have had more than one fracture in the preceding two years, but only one fracture could be reported.

Our finding that cigarette smoking was not a risk factor for fractures agrees with the findings reported from case-control studies by Paganini-Hill, *et al*,[9] and Kreiger, *et al*,[10] for hip fracture, and by Williams, *et al*,[11] for forearm fracture. On the other hand, Alderman, *et al*,[8] and Williams, *et al*,[11] showed an association between smoking and hip fracture. Williams, *et al*,[11] found a particularly strong effect among thin women, an effect we did not find.

It is possible that smoking increases the risk of osteoporosis,[1–4] but did not alter the risk of fracture among these nurses because they were too young. As the population ages, and sustains more osteoporosis and fracture, we will be able to examine the question further.

Alcohol intake is a risk factor for most injuries, including falls.[24,25] Most fractures are due to falls.[26] Indeed, more than 90 per cent of the Nurses' Health Study population who described the circumstances of their fracture on the 1986 questionnaire (over 600 respondents) had fallen. Alcohol consumption may also have the long-term effect of reducing bone density.[4–6] In addition, it can have the immediate impact of evoking risk-taking behavior and decreasing balance, resulting in more falls and fractures. The diet assessment questionnaire used in 1980 inquired about average daily consumption over the preceding year, and we do not have the blood alcohol content at time of injury. We might therefore expect to observe less of an alcohol-injury relationship than case-control studies which measure blood alcohol content at time of medical treatment.[24,25]

We observed no differences in the risk of fracture between teetotalers and those consuming up to 15 grams of alcohol per day. Alcoholism has been cited as a substantial risk factor for hip and forearm fracture.[14] We had no measure of alcoholism, but those drinking the most in our population did have a 24 per cent higher likelihood of fracture. Since the heavy drinkers comprised less than 15 per cent of our study

TABLE 4—Fracture Incidence by Age, Relative Weight (cases/10,000 person-years)

*Thin: relative weight less than 21 Kg/m^2
**Heavy Drinker: 15 or more grams/day of alcohol

population, even if their risk of fracture had been reduced to the level of non-drinkers, total reported fractures would have decreased only 3 per cent.

Relative weight may be associated with fractures for a variety of reasons. Heavier women, for example, may be larger boned, and have more bone mass to lose before the process of osteoporosis leads to critically low levels. Additional adipose tissue may provide more opportunity for estrogen production, and the fat itself may offer cushioning protection during a fall. Other studies of hip fracture,[9,14] and of forearm fracture,[8,14] as well as this study, find the thinnest women at somewhat higher risk for fracture.

Our finding that the combination of thinness and relatively heavy alcohol consumption dramatically increased the fracture risk (particularly among women over 50 years old) is provocative and deserves further research.

While this study has the advantage of being large and prospective, it suffers from several limitations. It included few elderly women, who are at greatest risk for fracture and subsequent mortality. Second, the 1982 and 1984 follow-up questionnaires combined hip and forearm fractures together, although they may be of different etiologies.[19] Finally, in this analysis we examine only four independent variables: age, cigarette smoking, alcohol consumption, and relative weight, although there are many other potential confounders.

Nevertheless, a conclusion that does emerge from the analysis is how little is explained by the three lifestyle variables examined. Most similar-aged women in the study—whether thin or fat, smoking or non-smoking, teetotalers or drinkers—generally had an equivalent chance of sustaining a hip or forearm fracture. Only the thin drinkers had a substantially higher risk, and they represented only 4 per cent of the population and 6 per cent of the fractures. The evidence suggests that otherwise beneficial habits such as avoidance of smoking and obesity may not significantly reduce the risk of fracture among middle-aged women.

Ford Foundation and Harvard University Honor Government Ingenuity

Ten creative state and local government projects addressing some of today's most difficult and seemingly intractable public policy problems were recently named winners in the 1988 Innovations in State and Local Government Awards Program, sponsored by the Ford Foundation and the John F. Kennedy School of Government at Harvard University.

Ranging from a welfare-to-work program to a housing integration initiative in Cleveland, Ohio's suburbs, to a project to house the homeless in San Diego, California, the winners received $100,000 grants from the Ford Foundation at a ceremony held September 30 at the National Press Club in Washington, DC. They include five statewide and four municipal programs, as well as one county-sponsored project selected from among 970 entries. The field was narrowed to 25 finalists last June. The 1988 winners are:

CALIFORNIA—*The City of San Diego's Single-Room Occupancy Residential Hotel Program* reverses the decline of privately-owned housing for the city's low-income population, and eases the crisis of homelessness by encouraging the private sector rehabilitation and construction of single-room occupancy hotels (SRO's).
COLORADO—*The City of Fort Collins' Land Development Guidance System (LDGS)* creates a new, flexible guide for urban planning and development by incorporating issues of land use, design, density, and location into a single decision-making process.
ILLINOIS—*Project Match of the Department of Public Aid* encourages welfare recipients to enter the workforce by helping them return to school, obtain job training, find and keep jobs, and advance in a career.
KENTUCKY—*Court of Justice of the Commonwealth of Kentucky* has replaced court reporters and audiotapes with videotapes in trial courts across the state, providing instantaneous records of court proceedings for lawyers and juries, and lowering the cost of justice.
KENTUCKY—*The Kentucky Department of Education's Parenthood and Child Education Program* stops the intergenerational cycle of illiteracy in rural areas by combining adult education with early childhood development.
MASSACHUSETTS—The state's *Industry Action Program* promotes competitiveness and job preservation in mature industries by providing the resources necessary to address problems in a specific region.
MISSISSIPPI—*The City of Tupelo's Municipal School District* is working in partnership with private citizens, business, city government, and local foundations to make Tupelo one of the top 10 public school systems in the nation.
MISSOURI—*The St. Louis County Police Department* has reduced the amount of time officers spend filing reports by some 80 per cent, with the first comprehensive automated system encompassing reporting, management, and investigation.
OHIO—*The Racial Integration Incentives*, developed by the City of Shaker Heights Department of Community Services and financed by The Fund for the Future of Shaker Heights, along with two other organizations, promotes racial integration in a cluster of area suburbs in eastern Cuyahoga County by attracting home buyers to areas where their race is underrepresented.
VERMONT—*The State of Vermont Department of Libraries* has created a Statewide Library Automation Project to make the state's public and private library collections available to every citizen.

The $4.5 million Awards program, a three-year initiative now in its third and final year, has attracted 3,000 entries from across the United States since 1986. The Ford Foundation plans to continue the program in a new expanded form beginning in 1990, in cooperation with selected universities in several regions throughout the country. For further information, contact the Ford Foundation, 320 East 43 Street, New York, NY 10017. Tel: (212) 573-5000.

Drug Abuse Discharges from Non-Federal Short-Stay Hospitals

JOSEPH C. GFROERER, BA, EDGAR H. ADAMS, ScD, AND MARY MOIEN, MS

Abstract. An analysis of inpatient drug abuse cases was done using the National Hospital Discharge Survey (NHDS). An estimated two million discharges with a drug abuse diagnosis occurred in non-federal short-stay hospitals during 1979–85, a figure which is believed to be an underestimate. Compared to other hospital inpatients, drug abuse inpatients are more likely to be male, ages 15–44, and other than White race. Increases in hospital use for drug abuse treatment were found to have occurred between 1979 and 1985, with discharge rates per 10,000 population increasing from 3.1 to 6.0 for drug dependence and from 3.8 to 7.7 for nondependent drug abuse. Concurrent increases in availability of hospital-based inpatient drug and alcohol treatment programs and insurance coverage for drug abuse treatment were found to have occurred during the same period. (*Am J Public Health* 1988; 78:1559–1562.)

Introduction

Data on people receiving treatment for drug abuse have been collected and analyzed for a number of years by the National Institute on Drug Abuse (NIDA).[1–6] Nevertheless, there are no published national data on patients treated for drug abuse as inpatients in short-stay hospitals.

The purpose of this paper is to analyze drug abuse treatment data from the National Hospital Discharge Survey (NHDS) for the period 1979–85.

In addition, this study will evaluate the usefulness of the NHDS as a data source for drug abuse descriptive epidemiology and surveillance. Because drug abuse is an illicit deviant behavior, data on trends and changes in drug use patterns are difficult to obtain. The availability of data from a variety of sources can serve to provide corroboration of findings and occasionally may highlight regional variability. The NHDS population includes drug abusers referred to hospitals from drug treatment programs and private physicians, as well as people coming into hospital emergency rooms who are admitted as inpatients. NIDA's Drug Abuse Warning Network (DAWN) indicates that over 40 per cent of emergency room episodes involving drug abuse result in admission to the hospital.[5] Because of this overlap, comparisons between DAWN and NHDS will be discussed.

Methods

Data Source

The NHDS is conducted by the National Center for Health Statistics (NCHS) on a continuous basis. The data are obtained from the face sheets of a sample of inpatient medical records that are abstracted from a national sample of non-federal short-stay general and specialty hospitals in the United States. The sample is updated periodically to account for changes in the universe, such as the opening of new hospitals. Approximately 195,000 medical records from 407 participating hospitals were sampled in the 1985 NHDS, representing approximately 0.5 per cent of all discharges from non-federal short-stay hospitals in the US in 1985.[7,8] The response rate for hospitals has always been over 80 per cent in the NHDS. Sample data are weighted to provide nationally representative estimates of hospital discharges. Estimates of relative standard errors are provided to users of the data in charts shown in NHDS reports which approximate relative sampling errors for a wide variety of estimates. Over a seven-year period, the approximate relative standard error of an estimate of 100,000 discharges would be 9 per cent, and for an estimate of 20,000 discharges it would be 13 per cent.

Information on patient characteristics, admission and discharge dates, expected method of payment, geographic region of hospital, medical diagnoses and procedures are collected. Diagnosis and surgical and nonsurgical procedures are coded using the International Classification of Diseases (ICD) system. Since 1979, *The International Classification of Diseases—9th Revision—Clinical Modification* (ICD-9-CM)[8] has been used. Up to seven ICD-9-CM diagnostic codes are produced from each abstract record, with the first-listed code usually representing the principal diagnosis.

Definitions and Analytic Methods

Drug abuse discharges were defined as those with any listing of the following diagnostic categories:

ICD-9-CM Code	*Description*
304	Drug dependence
305.2–305.9	Non-dependent abuse of drugs, excluding alcohol abuse and tobacco use disorder
965.0, 965.8, 967, 968.5, 969	Poisoning by drugs, including only opiates and related narcotics, pentazocine, sedatives and hypnotics, cocaine, and psychotropic agents

The "poisoning by drugs" codes were included in the drug abuse definition because these codes involve many drugs which are known to be widely abused such as opiates, pentazocine, sedatives and hypnotics, cocaine, antidepressants and tranquilizers. Drug abuse discharges that included an ICD-9-CM code for suicide (codes E950–E958) were included in this study. Suicide attempts are known from DAWN to be involved in many emergency room episodes for sedatives and tranquilizers. Specifically excluded were poisoning by aspirin, acetaminophen, anticonvulsants, and anesthetics (except cocaine).

Also excluded from the drug abuse definition were drug psychoses cases (ICD-9-CM code 292) that did not specifically mention one of the above listed drug categories. Analysis of these cases showed that most involved a "correct drug properly administered" (ICD-9-CM codes E930–E949) as causing the psychoses.

TABLE 1—Drug Abuse Discharges from Hospitals by Diagnostic Category, 1979–85

Diagnostic Category	ICD-9-CM Codes	Discharges in Thousands	
		First Listed	All Listed
Total drug abuse		829	1,998
Drug dependence	304	294	718
Opiates	304.0	74	177
Cocaine	304.2	14	41
Marijuana + hashish	304.3	25	99
Unspecified drug dependence	304.9	140	313
Non-dependent drug abuse (excluding alcohol, tobacco)	305.2–305.9	213	903
Marijuana	305.2	7*	51
Opiates	305.5	12	45
Cocaine	305.6	12	57
Unspecified drug abuse	305.9	173	742
Poisoning by drugs	965.0, 965.8, 967, 968.5, 969	322	449
Opiates and related narcotics	965.0	18	36
Pentazocine	965.8	12	19
Sedatives and Hypnotics	967	74	107
Cocaine	968.5	**	9*
Psychotropic agents	969	215	302

*Based on small sample (30–59 cases).
**Sample size too small to be reliable (less than 30 cases).

Data analysis involved tabulation of drug abuse discharges from 1979 to 1985. Weighted data were used for all tables, so that the data represent estimates of discharges from all non-federal short-stay hospitals in the United States. Only differences that are statistically significant at the .05 level are specifically mentioned in the text.

Results

An estimated 2 million hospital discharges involving drug abuse occurred during 1979–85, with 829,000 having drug abuse as the principal diagnosis. Table 1 shows the distribution of these discharges by specific diagnosis. A large proportion of drug abuse discharges on the NHDS file have the drug unspecified: 48 per cent of first-listed drug dependence diagnoses, and 81 per cent of first-listed non-dependent drug abuse diagnoses. Thus, comparison of population rates and totals among specific drug types is not possible.

Table 1 also shows that when drug poisoning is listed as a diagnosis, it usually is listed first (72 per cent of the 449,000 discharges), while this is not the case for the other drug abuse categories (41 per cent for drug dependence and 24 per cent for nondependent drug abuse). However, analysis of these other drug abuse categories suggests that even when drug abuse was not listed first, it was usually directly related to the first-listed diagnosis. In these cases, alcohol abuse or psychiatric disorders were usually listed first.

Drug abuse accounted for 0.8 per cent of an estimated 263 million discharges (excluding newborn infants) during 1979–85. Table 2 shows that drug abuse was more likely to be involved in discharges for males (54 per cent vs 40 per cent), for people ages 15–44 (76 per cent vs 40 per cent), and for races other than White (22 per cent vs 14 per cent).

While drug dependence and non-dependent drug abuse discharges appear to be very similar in terms of demographics, drug poisoning discharges are more likely to be female, more likely to be under age 15 or over age 44, and more likely to be White.

The drug poisoning discharges also are more likely to involve suicide attempts. While 18 per cent of drug poisoning discharges mention suicide (ICD codes E950–E958), less than 1 per cent of drug dependence and non-dependent drug abuse discharges do so. While keeping in mind the underreporting involved because most NHDS discharges for drug abuse are coded as drug unknown, the demographic characteristics of patients discharged for opiates, cocaine, and marijuana show interesting differences. Only 13 per cent of the opiate discharges were under age 25, while 32 per cent of cocaine and 58 per cent of marijuana discharges were under age 25. The marijuana discharges were more likely to be White than were opiate or cocaine discharges (73 per cent vs 47 and 50 per cent). Characteristics of patients discharged for poisoning by barbiturates, benzodiazepine tranquilizers, and antidepressants showed patterns similar to those for the combined drug poisoning category.

Drug abuse discharge rates are highest for 25–34 year-

TABLE 2—Demographic Distribution of All-listed Drug Abuse Discharges and Non-Drug Abuse Discharges, 1979–85

Characteristics	No Drug Abuse Diagnosis	Drug Abuse Diagnosis	Drug Dependence (304)	Non-dependent Drug Abuse (305.2–305.9)	Poisoning by Drugs (965.0 965.8, 967 968.5, 969)
Number of discharges (in thousands)	260,718	1,998	718	903	449
Sex					
% Male	40	54	61	59	38

45+	2.8	1.9	2.4	2.8

*Based on small sample (30–59 cases).
**Sample size too small to be reliable (less than 30 cases).

olds in all three diagnostic groups (Table 3). Males have higher rates for drug dependence and nondependent abuse while rates for drug poisoning are higher for females. Discharge rate trends by diagnostic group show that, while rates roughly doubled between 1979 and 1985 for both drug dependence and non-dependent drug abuse, rates for poisoning by drugs declined somewhat from 1979 to 1983, then increased in 1985 (Table 3). These trends occurred for both males and females, and for most age groups. Trends for specific drug types suggest very large increases in discharges for opiates, cocaine, and marijuana and relatively stable rates for poisoning by barbiturates, benzodiazepine tranquilizers, and antidepressants.

Discussion

The usefulness of NHDS data on drug abuse treatment is limited by both sampling and non-sampling errors. Because of the relatively low rate of discharge for drug abuse (compared to heart disease, cancer, or delivery, for example), sampling errors are unacceptably high for some subgroup estimates. To perform analysis of small subgroups, it is therefore necessary to combine data years; thus, analysis of annual data, such as for trends, can only be done for large population subgroups or for combined diagnostic categories. These approaches were employed in the tabulations shown in this paper.

The use of NHDS published relative standard error (RSE) charts also has its limitations. While these charts represent an approximation of the RSE for a wide variety of estimates, it is possible that errors for estimates of drug abuse discharges are somewhat larger than errors for other diagnoses because of the distribution of the drug abuse discharges among the hospitals in the sample. If this is the case, the RSE charts would underestimate the actual sampling errors associated with drug abuse discharge estimates.

The major non-sampling error problem with the NHDS drug abuse data involves the diagnostic coding. For a variety of reasons, it is likely that underreporting of drug abuse diagnoses occurs. First, the stigma associated with a patient having a drug abuse diagnosis may result in physicians in some cases not including drug abuse information. This practice could also be related to insurance coverage in that patients with no coverage for drug abuse treatment may be given other diagnoses that are covered by insurance. Also, physicians may not be sufficiently trained to recognize drug abuse, especially in comorbid conditions. In one recent study, physicians identified only 40 per cent of patients who suffered from alcohol or other substance abuse.[9]

Finally, since the NHDS abstractors primarily use only the face sheet, some diagnoses may not be identified, even if they are in the body of the medical record. Thus, it is likely that the proportion of hospital discharges related to drug abuse was larger than the 0.8 per cent estimated from the NHDS for 1979–85.

The use of face sheets may also lead to inaccurate coding of principal diagnoses, as was shown in an NHDS reliability study.[10] In that study, for patients found to have mental disorders, of which drug dependence and nondependent abuse are subgroups, 81 per cent of principal diagnoses were identified by NHDS, compared to 90 per cent of all-listed mental disorders that were identified by NHDS.

Thus the all-listed data are a better indicator of drug abuse involvement in the hospitalized population. A separate analysis, not tabulated here, showed that very little double-counting of discharges occurs, since less than 5 per cent of the discharges had diagnoses in more than one of the three major drug abuse diagnostic categories. However, specific drug type categories do involve some double-counting, especially the cocaine category. About half of the estimated 98,000 discharges for cocaine dependence or non-dependent abuse also had diagnoses of marijuana or opiate abuse, a finding which is consistent with other studies of cocaine treatment patients.[2,6]

It must also be stressed that NHDS estimates reflect counts of discharges, not people. It is unknown to what extent people have multiple inpatient hospital episodes during a year or a seven-year period.

Despite its limitations, the NHDS appears to be a useful source of drug abuse treatment data. As an ongoing nationally representative survey, it can be used to monitor trends in the use of inpatient hospitalization for drug abuse treatment. Patient characteristic and diagnostic information available from NHDS provide descriptive epidemiologic statistics for a population of drug abusers receiving the most intense and expensive type of care.

A comparison of NHDS and DAWN data[6] indicated generally consistent patterns in terms of patient characteristics (age, sex, and race) and trends. There are several major

differences in coverage between the two surveys, however. DAWN collects data from a non-random sample of hospital emergency rooms primarily in 27 major metropolitan areas, with a supplemental national panel of emergency rooms outside those areas. Although over 40 per cent of the drug-related emergencies are admitted as inpatients and thus become part of the NHDS universe, over half are released without being admitted.[5] Similarly, many NHDS drug-related cases are not admitted through the hospital emergency room and are therefore not eligible for DAWN. Hospital admissions may reflect chronic conditions rather than the acute conditions generally seen in emergency rooms. Another difference in the two surveys is that the NHDS includes some short-stay specialty hospitals, while DAWN includes only general hospitals.

Nevertheless, similarities in the DAWN and NHDS data suggest that despite the large proportion of NHDS cases with unknown drug, the discharges that do specify drug provide useful information on the characteristics of drug abuse discharges. However, for barbiturates, benzodiazepine tranquilizers, and antidepressants, DAWN metropolitan area and national panel data indicate decreases while NHDS data do not do so. Since NIDA is currently implementing a nationally representative sample in DAWN, comparisons between NHDS and DAWN will be much more informative in the near future.

An interesting finding from the NHDS data is the sharp increase in utilization of hospitals for drug abuse treatment between 1979 and 1985, a period during which the prevalence of drug use in the US population was stable or declining, with the exception of cocaine use.[11] This increase in hospital discharges may be related to increasing availability of hospital care and the increasing availability of insurance coverage for drug abuse treatment. Availability of hospital inpatient treatment for drug abuse can be measured by the number of community hospitals which have alcohol/chemical dependency inpatient units and by the number of beds in those units. The trend in availability of these units[12–15] closely parallels trends in discharge rates for drug dependence and non-dependent drug abuse (Table 3). A Department of Labor survey of medium and large companies[16,17] estimated that 36 per cent of workers in these companies had drug abuse treatment coverage in 1982, while 59 per cent had coverage in 1985. Also, increase in the demand for treatment may be occurring, as the drug-using cohorts of the 1960s and 1970s become older and the long-term health consequences of chronic drug use begin to emerge. Moreover, data from clients in drug abuse treatment facilities suggest a lag period of several years between first use of drugs and first entry into treatment.[18,19] Thus, an increase in treatment demand would be expected to follow by several years the increases in prevalence of drug use which occurred in the 1970s. Trends toward more dangerous patterns of use (such as smoking cocaine and polydrug use) in recent years may also be influencing treatment demand. Finally, it is also possible that physicians are becoming more adept at recognizing patients' drug abuse problems.

In summary, the NHDS drug abuse data are useful as a descriptive epidemiologic surveillance tool which when used with other data can serve to increase our understanding of drug abuse problems and shifting treatment demand. Users should be aware of the limitations of the data, however, particularly the likelihood that drug abuse diagnoses are underreported, with the implication being that the NHDS data underestimate the actual level of hospital discharges involving drug abuse.

Prevention of Lower Extremity Stress Fractures: A Controlled Trial of a Shock Absorbent Insole

Lytt I. Gardner, Jr., PhD, Joseph E. Dziados, MD, Bruce H. Jones, MD, John F. Brundage, MD, John M. Harris, MD, Robert Sullivan, DPM, and Paul Gill, DPM

Abstract: A prospective controlled trial was carried out to determine the usefulness of a viscoelastic polymer insole in prevention of stress fractures and stress reactions of the lower extremities. The subjects were 3,025 US Marine recruits who were followed for 12 weeks of training at Parris Island, South Carolina. Polymer and standard mesh insoles were systematically distributed in boots that were issued to members of odd and even numbered platoons. The most important finding was that an elastic polymer insole with good shock absorbency properties did not prevent stress reactions of bone during a 12-week period of vigorous physical training. To control for the confounding effects of running in running shoes, which occurred for about one and one-half hours per week for the first five weeks, we also examined the association of age of shoes and cost of shoes with injury incidence. A slight trend of increasing stress injuries by increasing age of shoes was observed. However, this trend did not account for the similarity of rates in the two insole groups. In addition, we observed a strong trend of decreasing stress injury rate by history of increasing physical activity, as well as a higher stress injury rate in White compared to Black recruits. The results of the trial were not altered after controlling for these factors. This prospective study confirms previous clinical reports of the association of stress fractures with physical activity history. The clinical application of a shock absorbing insole as a preventive for lower extremity stress reactions is not supported in these uniformly trained recruits. The findings are relevant to civilian populations. (*Am J Public Health* 1988; 78:1563–1567.)

Introduction

Stress fractures and stress reactions of the lower extremities have long been considered a hazard of military life and are frequently associated with road marching or high intensity physical training. The occurrence of these injuries has been noted for many decades,[1–5] but only since the mid-1970s have studies with rate calculations been published, yielding a better idea of the serious nature of this problem. Eight studies since 1974 have documented that the stress fracture rate in military recruits varies from 1 to 4 per cent in males and from 10 to 15 per cent in females.[6–13] Injuries of this type, particularly if they occur in the femur, have a protracted hospital course, can be permanently disabling, and lead to a higher rate of medical discharge in affected trainees.

The ideal military training program would allow trainees to pass through a period of bone resorption activity, followed by bone replacement activity, without suffering a stress fracture or periosteal stress reaction.[13] Prevention in military training has therefore focused on reducing the intensity of training in the first few weeks, the period of maximal bone resorption, particularly for trainees who are not physically fit at entrance. Current US Army training policy requires unfit trainees to be exercised more gradually during the first three weeks.*

One characteristic of the training environment that can be modified easily is the amount of cushioning provided by footwear during training. Lack of cushioning in shoes has been hypothesized for some time as a cause of running injuries.[14–17] Consequently, running shoes are permitted to be worn during training runs in the military in place of the military combat boot.[18] The military combat boot was not designed to be shock absorbent, but to protect the foot and ankle from inversion injuries. An evaluation of Army combat boots found them to be inferior to running shoes in impact protection, flexibility, and energy retrieval.[19] In spite of these shortcomings, many hours of running, marching, calisthenics, and drill take place in combat boots. The simplest means for enhancing impact protection of the boot is to place within it a shock-absorbing insole. If it were to prove efficacious in preventing lower extremity injuries, such an insole could easily be added to the military footwear currently issued to each recruit.

The Sorbothane insole (IEM Orthopaedics, Aurora, Ohio), a viscoelastic polymer, was manufactured to absorb up to 95 per cent of the impact stress transmitted from the ground to the lower extremities. The following report describes a 1985 trial of the effect of Sorbothane insoles, as compared to a standard insole made of mesh, in prevention of stress fractures and stress reactions of bone.

Methods

Subjects

The subjects of this study were 3,025 United States Marine basic training recruits, with a mean age of 20.0 years ± .02, range 18 to 41, who underwent 12 weeks of basic training at the Marine Training Center at Parris Island, South Carolina. Sixty-seven per cent of the trainee population was White non-Hispanic, 24.6 per cent was Black non-Hispanic, 5.6 per cent was Hispanic, 0.7 per cent was Native American, and 1.5 per cent was of other ethnic origin.

Questionnaire

Recruits completed a questionnaire after hearing each item read aloud by an instructor to ensure comprehension. Questions were included which determined the recruits' usual physical activity status (very active, active, average, not very active, inactive) prior to their arrival at Parris Island, and the age, condition, and cost of their running shoes used during training.

Physical Training Program

Trainees participated in 92 hours of physical training (road marches, calisthenics, running, rappelling, and swimming) and 41.5 hours of drill and ceremony during a 12-week stay at Parris Island. Of the time devoted to physical training, only the hours devoted to swimming and ceremony (19 hours) did not expose the trainees to the risk of lower extremity injury. Since 1976, the Marine Corps has allowed trainees to run in footwear other than boots, and about nine hours of training were spent running while wearing running shoes (recruit-purchased, not issued). Most of the running in shoes (80 per cent) occurred during the first five weeks of training. While the style and condition of the running shoes were not under control, the answers to questions about the condition of the shoes allowed some control for their effect.

Training was done by platoon unit—a group of approximately 65 persons who shared the same sleeping and eating facilities. During the first week, all trainees were required to take a diagnostic physical fitness test consisting of a one and one-half mile run, pull-ups, and situps. Passing a final physical fitness test consisting of a three-mile run, pull-ups, and situps was a requirement for graduation. Two long marches (seven miles and 10 miles) in boots and full combat equipment occurred in the 4th and 8th weeks, respectively.

Trial Design

Boots with polymer insoles were issued to trainees who were assigned to even-numbered platoons. Boots with a standard mesh insole were issued to members of odd numbered platoons. Exchanging or losing the insoles was minimized in two ways. First, virtually no interaction among trainees from different platoons was permitted, and all trainees within each platoon had the same insole type. Second, trainees were told at the beginning of training and periodically during training that they were to leave the insoles in their boots. Equipment inspections enforced compliance.

Ascertainment of Injury Endpoints

All Marine recruits who had lower extremity injuries were evaluated at a medical clinic on Parris Island. Injury information for this study was recorded on clinical data forms at the time of the clinic visit. Patients were transferred to Beaufort Naval Hospital for lower extremity x-rays.

Two radiologists independently evaluated the radiographs of injured recruits. The first radiologist, at Beaufort Naval Hospital, gave the primary radiologist's reading of the films. After the study was completed, the x-ray films were re-evaluated by another radiologist at Walter Reed Army Medical Center, Washington, DC. Both radiologists were blinded with respect to insole status and the second review was blinded concerning the primary evaluation.

Endpoint classification was based on functional impairment rather than solely on radiographic demonstration of a clear disruption of the integrity of bone cortex. Thirty-eight trainees had either x-ray-confirmed stress fractures or clinically serious stress reactions with x-ray evidence compatible with stress injury (cortical tunneling or lucency). Since recruits with pain in the lower extremities were managed conservatively, many stress reactions were prevented from progressing by repeated visits to the Parris Island medical clinic, which was open 24 hours a day. A number of individuals had only one film taken and, because of the delay in appearance of radiographic evidence following onset of symptoms, these early x-rays were frequently negative. Rather than drop from the analysis all persons with only early x-ray films, we pooled together x-ray-confirmed stress fractures with stress injuries having an incomplete set of radiographs but clinically significant symptoms and referred to them all as stress fractures.

The distribution of the 38 stress fractures was femur (5), tibia (14), fibula (5), calcaneous (1), and metatarsal (13). Most of these injuries were unilateral, but bilateral injuries occurred in the tibias of four recruits, and in the femurs, calcanei, or metatarsals of one recruit each.

Statistical Analyses

Fisher's exact test was employed to test the significance of proportions compared in two by two tables.[20] Where questionnaire responses followed an ordered sequence, a chi-square test for trend was employed.[21] All data were collected on mark-sense forms and edited and analyzed using version 4.0 of the Statistical Analysis System.[22]

Results

Table 1 presents fracture rates by age, ethnicity, and activity status. With only 37 recruits above age 25, the 21+ age group mainly represents the ages 21 to 25. Adjusted for physical activity, the relative risk for older vs younger recruits was 1.71. Whites, compared to other racial and ethnic groups, had a relative risk of 2.45. Intrinsic racial differences in susceptibility to stress fractures are given some support by these data.

Previously inactive trainees were at much greater risk, over 10 times the average of the other four activity categories. The inverse relation of risk to reported physical activity is strong in these data: the chi-square for linear trend was highly significant. Compared to trainees with above average activity levels, the relative risk of fracture for all others was 2.40 (95% C.I. = 4.58, 1.26).

As seen in Table 2, the fracture rate for the polymer insole group was slightly higher (1.35 per cent), but not very different from the rate in the standard insole group (1.13 per cent). Activity levels were similar in the two groups. In the less active subgroup and the more active subgroup, the fracture rates did not vary much by insole type.

We examined the fracture rates by location of stress injury (Table 3) to see whether the protective effect of increased shock absorption could be localized to the foot. We found no such effect.

TABLE 1—Stress Fracture Rates by Age, Ethnicity, and Activity

Variables	Fractures	Trainees	Rates (%)
Age (years)			
18–20	21	2074	1.01
21+	17	934	1.82
Summary* Relative Risk 18–20 vs 21+ = 1.71 (95% CI: 0.92, 3.21)			
Ethnicity

Below Average	5	224	2.20
Average	15	924	1.62
Active	11	1197	0.91
Very Active	4	638	0.62

*Adjusted for history of reported physical activity (5 levels).

TABLE 2—Stress Fracture Rates by Boot Insole Type

	Total Group	Polymer	Mesh	Relative Risk	95% CI
N/PAR	38 /3025	21/1557	17/1468	1.17	(.62, 2.2)
Per Cent	(1.26%)	(1.35%)	(1.13%)		
Physical Activity = Average or Below	23 /1173	13/589	10 /584	1.29	(.57, 2.9)
	(1.96%)	(2.21%)	(1.71%)		
Physical Activity = Active or Very Active	15 /1835	8/960	7/875	1.04	(.38, 2.9)
	(0.82%)	(0.83%)	(0.80%)		

Since the cushioning and support from running shoes deteriorates with age, we examined whether the age of shoes was equivalent for polymer and standard insole groups. A modest trend of increasing fracture rates by age of shoes was observed (Table 4). The crude relative risk of 1.17 was unchanged after adjusting for age of shoes with two levels (less than one month, greater than one month). Cost of shoes in relation to fracture rates was examined. The rates varied only slightly among three categories of cost, with no apparent trend (Table 5).

Finally, we examined the differences for polymer vs mesh groups in a category comprising four other major injuries: plantar fasciitis, ankle sprains, knee strains and sprains, and achilles tendonitis (Table 6). Once again, no protective effect from the polymer insole was apparent.

Discussion

Published tests of the efficacy of shock absorbent materials in footwear have been few. On the other hand, many citations can be found which recommend the use of shock absorbing shoes or shock absorbent insoles based on a review of clinical cases.[14–17] Our review of the literature uncovered only one prospective study of the efficacy of shock absorbing insoles in preventing any type of overuse injuries. A 1985 study of 90 US Coast Guard recruits reports cushioned insoles successful in reducing "shock impact and shearing injuries"[23]; however, the impact and shearing injuries referred to were foot bruises, calluses, and blisters, not stress fractures or stress reactions. An unpublished 1986 report on the frequency of lower extremity injuries among 555 female Army basic trainees found no difference in stress fracture or stress reaction rates between trainees wearing a Sorbothane insole compared to those wearing a standard mesh insole.**

TABLE 3—Injury Rates by Insole Type Stratified by Injury Location

Location	Injury Type	Insole Type: Polymer	Insole Type: Mesh
Above the Foot	Stress Fractures	10 /1557 (0.64%)	14 /1468 (0.95%)
	Other Injuries	233 /1557 (15.0%)	253 /1468 (17.2%)
Foot	Stress Fractures	11 /1557 (0.71%)	3 /1468 (0.20%)
	Other Injuries	47 /1557 (3.01%)	38 /1468 (2.59%)

While observations on injuries in military training are not always generalizable to the general population, injury types in this and other military populations resemble civilian population reports. In basic training populations in the Army, five injury types are repeatedly cited as accounting for over 50 per cent of all training injuries: stress fractures, overuse injuries of the knee, plantar fasciitis, achilles tendonitis, and ankle sprains.[6,12,24] These same five injury types are cited as accounting for over 50 per cent of all injuries in civilian running and jogging programs.[14,16,25]

The uniformity of Marine training is advantageous for determining the effect of a simple training modification—the addition to the boot of a shock absorbing viscoelastic insole. Each drill instructor, platoon, and training company follows the same program during the 12-week training cycle. This rigid pattern is in contrast to the exercise patterns of runners presenting at an orthopedic or sports medicine clinic, where the entire spectrum of activity is represented.

The stresses of physical training were greater for those trainees who were initially physically unfit. Previous studies have also noted the association of fitness with injury risk, but they used data collected retrospectively, after the injury had occurred.[26] In contrast, the present study recorded responses to questions before training began. A simple multiple choice response to the question, "How would you describe your life before coming to Parris Island?", proved remarkably sensitive in discriminating trainees at risk of significant stress reactions. For those 25 categorized as "inactive" prior to their training, three (12 per cent) suffered a significant stress reaction. The other responses were associated with progressively lower rates of bone injury.

In civilian populations, the most frequently encountered abrupt change in physical activity is increased or newly adopted running, referred to as "training errors". These errors may be the most important cause of running injuries.[15,16] These clinical observations reflect the importance of what Powell, *et al*, have called "the stability of running habits."[27] Although we cannot give quantitative guidance from these data about the amount of activity change that leads to an injury risk, we can say that previously inactive recruits had a 10-fold excess risk of clinically significant stress reactions during basic training relative to the rest of the recruit population. The impact of the inactive group on the Marines (25 of 3,025) is small, but for the general

population that proportion, and the injury consequences, would be much higher. The traditional recommendation to beginning runners (and the military's requirement for physically unfit trainees) to start slowly and to build up progressively the frequency, intensity, and duration of running, would seem well supported as a policy for preventing significant stress reactions of bone.

The distribution of stress reactions in this study (71 per cent of the total found in tibia or metatarsal) follows closely that observed in similar studies.[11,28] The authors of one study correlated their findings with the use of a heel snap to mark the cadence while marching. The heel snap has since been discontinued.

We observed a slight excess of clinically significant stress reactions of the metatarsals and calcanei in those recruits who used the Sorbothane insole. This excess was reflected, to a lesser extent, in higher overall injury rates below the ankle in the polymer insole group. The picture was reversed above the ankle, with a slight excess of fractures in the mesh insole group, and likewise an excess of all other types of injuries in the mesh insole group. Whether this pattern is causally related to the insole remains an intriguing question that needs testing.

These data also confirm earlier studies' reports of an excess of stress fractures or stress reactions in Whites compared to Blacks.[9] One explanation for this finding could be the lesser bone density and bone mass observed in Whites compared to Blacks.[29–32] If racial differences in bone density are important predictors, studies which can account for both bone density and physical activity history need to be done.

Of the 92 hours of physical training each recruit experienced, nine were spent in running shoes without an insole. Although we did not study running shoes in detail, the age of the shoes and the price paid provided information about condition of the shoes. Price, a correlate of overall quality, perhaps of shock absorbency, did not affect fracture rates, but increasing age of shoes did. The age of the shoe may indicate the degree to which its shock absorbent material has been compacted. On the other hand, the mechanical support provided by a shoe is also adversely affected by age. Without more data, cushioning effects cannot be separated from support effects. We also cannot assess the efficacy of shock absorbing insoles for moderate vs extreme amount of running.

Our findings suggest that the relation between footwear and lower extremity injuries is complex, that the simple model of the lower extremity as a projectile impacting upon shock absorbent material is not dynamic enough, and that shock or stress absorbency derives from the physiology and biomechanics of the lower extremities as well as from the physics of footgear. The most important modifiable factor in injury prevention was physical conditioning of the lower extremities.

Abstracts Sought for 1989 Public Health Conference on Records and Statistics

The 22nd biennial Public Health Conference on Records and Statistics will be held in Washington, DC, July 17–19, 1989. The conference is sponsored by the National Center for Health Statistics and serves as a major national forum for the latest advances in public health statistics.

The theme of the 1989 conference is "Challenges for Public Health Statistics in the 1990s." The conference offers an opportunity to assess the demands for health statistics in the next decade and how those demands can be met. Three major areas will be addressed:

- Promotion and Prevention
- Surveillance and Epidemiology
- Targeting Services

Presentations will be organized in sessions focusing on policies, programs and services; methodological and analytical issues; and trends, projections and goals. The conference will highlight topics of current health importance such as HIV (human immunodeficiency virus) Infection, Aging, Injuries, Maternal and Infant Health, Chronic Diseases, Preventable Morbidity and Mortality, Environmental Issues, and Ecological Analyses, as well as a special session on Marriage and Divorce Statistics.

Both invited and contributed papers will be featured. To be considered for presentation, NCHS must receive an abstract of a contributed paper by January 13, 1989. For more information on the call for papers, instructions on submitting an abstract for consideration, or to receive a conference invitation, contact Nancy Hamilton, OPEP, PHCRS, National Center for Health Statistics, 3700 East-West Highway, Room 2-12, Hyattsville, MD 20782. Tel: (301) 436-7122.

posttest counseling in this study, diverse forms of information and social support were given by the nurses who maintained contact with the participants. Testing was voluntary, with informed consent and under the strict condition of confidentiality. Because ethical and practical considerations prohibit experimenting with the factors mentioned above, their individual contribution to the effect of testing cannot be distinguished.

APPENDIX

The relative importance of a sexual technique was determined by the computation of so called deviation contrasts, or deviations from the grand means.[10–12] A practical description of this procedure is found in the SPSSX Users Guide,[12] pp 494–495. New variables were computed for each individual and each sexual technique on pretest, posttest, and follow-up, by subtracting from the number of partners on a specific technique, the mean of the number of partners with whom the remaining techniques were performed. An example may clarify this procedure: if an individual performs masturbation with two partners, orogenital intercourse with six partners, and anogenital intercourse with eight partners, the relative importance of masturbation is $2-(6+8)/2=-5$, of orogenital intercourse $6-(8+2)/2=1$, and of anogenital intercourse $8-(2+6)/2=4$. Twelve months later, if this individual practices masturbation with eight partners, orogenital intercourse with two partners, and anogenital intercourse with zero partners, the relative importance of masturbation has increased to $8-(2+0)/2=7$, of orogenital intercourse has decreased to $2-(8+0)/2=-2$, and of anogenital intercourse has decreased to $0-(8+2)/2=-5$. It is concluded that a shift has occurred in the pattern of practiced sexual techniques from orogenital and anogenital intercourse in the direction of masturbation. Sexual techniques included in this procedure were: oral, manual, orogenital, anogenital, oroanal, anobrachial, anodigital, dildo use, rectal douching, scat and watersports.

Changes in the Distribution of Physicians in Rural Areas of Minnesota, 1965-85

TERRY DENNIS, MD

Abstract: The purpose of this study was to assess changes in the physician-population ratio in non-SMSA Minnesota counties between 1965 and 1985 using county specific data published by the American Medical Association. The physician-population ratio actually decreased by 2 per cent for primary care physicians and by 11 per cent for family practitioners in the non-SMSA counties. The large increase in the number of physicians in Minnesota has not translated into improved access to primary care physicians in Minnesota's rural areas. (*Am J Public Health* 1988; 78:1577–1579.)

Introduction

Physician manpower policy in the late 1960s was dominated by a shortage of primary care physicians in rural and inner-city areas. Federal and state governments responded to this problem by funding massive increases in the number of medical school graduates, the establishment of new primary care residency programs, and development of primary care service programs for the underserved.[1] Events in Minnesota which have mirrored the national response over the last 20 years resulted in a 50 per cent increase in the number of physicians in Minnesota between 1965 and 1977.[2]

By the late 1970s, concern had shifted from a physician shortage to an impending physician surplus.[3] It was asserted that a surplus of physicians would induce enough underutilized physicians to "diffuse" from the larger cities into ever smaller communities and resolve the physician manpower problem.[4,5]

This study was designed to assess whether "diffusion" was in fact occurring in Minnesota and, if so, whether it was sufficient to redress the deficits in primary care physicians identified 20 years ago.

Method

Population figures for each county in Minnesota were obtained from the 1970 census and projections of 1985 population.[6] Counties were classified as either "SMSA" or "non-SMSA" based on the 1977 US Department of Commerce definition of Standard Metropolitan Statistical Areas. The "non-SMSA" counties were then divided into the

following groups using their 1985 population: less than 10,000; 10,000 to 24,999; 25,000 to 60,000 population.

Data on the distribution of non-federal Minnesota physicians by specialty group and county were obtained for the years 1965, 1975, 1980, and 1985 from American Medical Association publications.[7–10] The AMA data were categorized into four specialty groups:

- *Family Practice* which included family and general practitioners;
- *Medical Specialties* which included internal medicine, pediatrics, and their subspecialties;
- *Surgical Specialties* which includes general surgery, neurological surgery, obstetrics and gynecology, plastic surgery, colon and rectal surgery, thoracic surgery, and urology;
- *Other* which consists of all other specialties, hospital-based and unclassified physicians;
- Physicians classified as "Inactive" or "Other Professional Activity" were excluded.

The Family Practice and Medical Specialties groups were also combined into a single "Primary Care" group. This excludes Obstetrics-Gynecology and other surgical specialists as primary care providers.

The trend and change from 1965 to 1985 in the physician-population ratio for each specialty and county group were tabulated to assess if net "diffusion" was occurring.

Results

Table 1 illustrates the physician-population ratio in Minnesota by specialty group and category of county during the period 1965-85. The non-SMSA counties exhibited a marked decrease in family physician-population ratio from 1965 to 1975. Since 1975, replacement physicians have moved into these communities but the ratio remains higher than in 1965. In contrast, the family physician-population ratio in SMSA areas increased by 11 per cent during the two decades.

In contrast to family practitioners, medical, surgical and other specialists have increased in all communities. If internists, pediatricians, and family physicians are combined into a "Primary Care" classification, it is evident that the medium size counties (25,000 to 60,000 population) have experienced a slight increase in the primary care physician-population ratio (Table 2) while the smaller counties have experienced a decrease. The SMSA counties have had a major increase in this ratio although many of the physicians may be subspecialists in internal medicine and pediatrics. Despite the increase in non-primary care specialists, the total physician-population ratio has decreased in the counties of less than 25,000 population.

Table 3 summarizes these findings for all non-SMSA counties in Minnesota. There were fewer "Family Practice" physicians per population in 1985. Even when "Medical Specialties" are included with family physicians, there has been essentially no change in "Primary Care" physicians per population over the 20-year period. There are obviously more surgeons and other specialists available than in 1965, and an increase of 15 per cent in the overall physician-population ratio has occurred.

TABLE 1—Physician/Population (per 100,000) Ratio by County Population, Minnesota 1965–85

Practice Group/Year	Non-SMSA <10,000	Non-SMSA 10,000 to 24,999	Non-SMSA 25,000 to 60,000	SMSA

1985	54.02	57.08	95.59	244.77

Discussion

The information presented here demonstrates that despite a greater than 60 per cent increase in the number of physicians, the goal of increasing the primary care physician-population ratio in Minnesota's smaller communities has not been achieved.

In contrast to the inadequate "diffusion" of primary care providers, other specialists are rapidly increasing in smaller communities. These specialists have undoubtedly brought new medical services to outstate Minnesota and taken over certain duties in surgery, orthopedics, and obstetrics from the core practice of family physicians. The amount and quality of primary care these surgical specialists are attempting to deliver is not known.

The potential relief offered the primary care specialists by the presence of their surgical colleagues must be considered in light of the changes within the primary care specialties themselves. The demographic and specialty characteristics of primary care providers have dramatically changed during the last 20 years. Some evidence[11–14] suggests that these changes have decreased the potential capacity of each physician.

This study did not include osteopaths. However, review of directories of the American Osteopathic Association[15,16]

TABLE 2—Primary Care/Population (per 100,000) Ratio by County Size, Minnesota 1965–85

Years	Non-SMSA <10,000	Non-SMSA 10,000 to 24,999	Non-SMSA 25,000 to 60,000	SMSA
1965	51	50	52	52
1975	40	40	46	59

Surgical Specialties	9	14	58
Other	7	12	81
Total	65	76	18
Primary Care	51	50	−2

reveals that 13 more osteopathic physicians were in non-metropolitan Minnesota in 1985 than in 1968. Seven of the new osteopaths were in counties of less than 10,000 population and would result in a small (6 per cent) increase in the physician-population ratio in the smallest counties. Aside from these smallest counties, the additional osteopaths would have had a negligible impact on the overall situation in non-metropolitan Minnesota.

The trends identified in this study may or may not reflect those in other areas of the US. Future investigations should also identify the impact of the changing demographic profile of physicians on primary care availability in smaller communities and the extent to which physicians classified as non-primary care specialists actually provide primary care, when they are located in smaller communities.

The Accuracy of Industry Data from Death Certificates for Workplace Homicide Victims

HAROLD DAVIS, MD

Abstract: This study compared death certificate data on usual industry for workplace homicide victims in five urban Texas counties, with medical examiners' data on the industries where victims were working when injured. The overall positive predictive value of the death certificate data was 72 per cent. Death certificate data on usual industry underestimated the number of victims working in high-risk industries when injured, partly because of victims whose usual industry was recorded as student, housewife, or military personnel. (*Am J Public Health* 1988; 78:1579–1581.)

Introduction

To determine the industry of a worker who was a homicide victim, recent studies[1–3] have used death certificate data on usual industry (the industry in which a person worked during most of his/her working life). However, at the time of injury, a workplace homicide victim might not have been working in his/her usual industry (e.g., educational services) but rather in a second, different one (e.g., gasoline service stations). Therefore, death certificate data on usual industry might not accurately document the victim's industry when injured. Although studies have examined the accuracy with which death certificate data document a person's usual industry,[4–7] none have examined the accuracy with which these data document a workplace homicide victim's industry at the time of injury.

In most urban Texas counties, medical examiners investigate all injury-related deaths. For workplace homicides, the medical examiners' records usually contain information on the victim's industry when injured. Using medical examiners' data from five urban Texas counties as the standard, I studied the extent to which death certificate data on usual industry accurately document the industries where victims were working when injured.

Methods

For the deaths they investigate, medical examiners in Texas complete certain parts of death certificates, including those on cause of death; accident, suicide, or homicide; injury at work; how a fatal injury occurred; and place of fatal

injury (e.g., bar, street). Funeral directors also complete parts of these death certificates, including that on usual business or industry.

Cases of workplace homicide were identified via two steps. First, a review of Texas death certificates identified the death of any person who was ≥16 years old; whose cause of death was coded by the International Classification of Diseases (8th[8] and 9th[9] revisions) to "homicide" (ICD Codes E960-969); who was injured in Texas; whose death certificate had a positive response to "injury at work?"; and who died in the period 1975 through 1984 in Harris, Dallas, Tarrant, Bexar, or Travis Counties (which contain the cities of Houston, Dallas, Fort Worth, San Antonio, and Austin, respectively). In the second step, medical examiners' records on these deaths were reviewed to confirm that they were in fact homicides that had occurred in the workplace.

Data from death certificates on usual industry and from medical examiners' records on industry when injured were assigned three-digit codes according to the 1980 census industry classification system.[10] The coding system has been described previously.[2] A death certificate entry was considered accurate if its three-digit industry code was identical to that for the entry on the medical examiner's record. Only cases with industry data on both the death certificates and medical examiners' records were included.

Results

Of the 533 confirmed cases included in the analysis, 386 had death certificate industry data that were accurate, yielding a positive predictive value of 72 per cent (Table 1). The positive predictive value of death certificate data on male victims (320 of 446 industries accurate, 72 per cent, 95% CI 67–76 per cent) was similar to that for female victims (66 of 87 industries accurate, 76 per cent, 95% CI 66–84 per cent).

Of the industries previously shown to have high risks of workplace homicide (Table 1), six of seven had death certificate usual-industry data with positive predictive values for industry when injured of ≥89 per cent. In contrast, the death certificate usual-industry entries "student", "military personnel", and "housewife" never correctly described the victims' industries when injured. For the 28 victims with these usual-industry entries on their death certificates, medical examiners' records revealed that when injured they were working in food-bakery-and-dairy stores (seven persons), gasoline service stations (seven), eating-and-drinking places (five), or other industries (nine).

For five of seven high-risk industries, death certificate usual-industry data underestimated the number of victims working in them when injured (Table 1). This was most marked for eating-and-drinking places, which had 96 persons listed on medical examiners' records but only 61 persons listed with that usual industry on death certificates.

Of the 147 death certificates whose usual-industry data did not reflect the industry when injured, 60 (41 per cent) had death certificate description-of-injury or place-of-injury portions that correctly described the victims' industries when injured. For the other 87 death certificates, these portions either had no description of the victims' industries (86 of 147 death certificates, 59 per cent) or an incorrect description (one of 147, <1 per cent).

TABLE 1—Accuracy of Death Certificate Industry Data for Workplace Homicide Victims, 16 Years old or older, 1975–1984, in Five Urban Texas Counties[a]

Industry	Medical Examiners' Records (industry when injured)	Death Certificates (usual industry)

[a]Harris, Dallas, Tarrant, Bexar, and Travis Counties.
[b]Accurate indicates that death certificate data on usual industry correctly described a decedent's industry when injured.
[c]PPV = positive predictive value (95% confidence intervals).

Discussion

This study found that when the usual industry entered on a workplace homicide victim's death certificate is a high-risk one, the victim very likely was working in that industry when injured. In contrast, when the usual industry entered on the death certificate is a low-risk one (and especially if the entry is student, housewife, or military personnel), the victim often was not working in that industry when injured but in a high-risk one. Due to the disparities between the usual-industry entries on death certificates and the industries where victims were actually working when injured, death certificate data on usual industry tend to underestimate the number of victims working in high-risk industries when injured[4].

Death certificate data on usual industry can correctly identify which industries have high risks of workplace homicide, but estimation of these risks might be made more accurate by supplementing the usual-industry data with data from the description-of-injury and place-of-injury portions of death certificates. Nevertheless, in 59 per cent of deaths with inaccurate usual-industry data, these latter two portions do not describe the victims' industries at the times of injury. Persons completing description-of-injury and place-of-injury portions of death certificates can increase the usefulness of death certificates for the study of workplace homicides by including in these portions descriptions of the industries where victims were working when injured.

Nurse Administration of Sleep Medication: A Comparison of Registered Nurses and Licensed Practical Nurses

PAMELA A. ROBERS, PHD, TERRI SMITH MOORE, MBA, AND BONNIE L. SVARSTAD, PHD

Abstract: This study examines differences in the administration of PRN (pro re nata or give "as needed") sleep medication between licensed practical nurses and registered nurses working in long-term care facilities. Work characteristics, characteristics of the residents cared for, and the extent of orders and administration of PRN sleep medications were similar in the two groups. No significant differences in the administration of PRN sleep medication were found. (*Am J Public Health* 1988; 78:1581–1583.)

Introduction

Administration of medication in long-term care facilities (LTCFs) is a function performed primarily by licensed practical nurses (LPNs) and registered nurses (RNs). According to the National League for Nursing, "LPNs/LVNs are prepared to function under the guidance of a registered nurse or licensed physician. . ."[1] However, one report indicates that even in the structured setting of the hospital, nine out of ten RNs responded that, in their facility, LPNs routinely administered medications without the direct supervision of an RN.[2] In the less structured nursing home setting, the autonomy of LPNs is likely to be even greater than in hospitals.[3–6]

When medications are prescribed PRN (pro re nata or give "as needed") the ultimate decision is delegated to the nurse in charge of administering medication. Studies examining PRN prescribing in LTCFs report that residents have an average of three to four orders for PRN medications during a time frame of 30 days or less.[7–16] Yet little is known about the factors affecting the nurse's medication decisions.

Sleep medications are commonly ordered for nursing home residents,[8,13,16,17–19] and about 50 per cent of sleep medication orders are written for PRN administration[13,20]; elderly individuals are particularly sensitive to and more likely to experience adverse effects than would younger individuals.[21–30] We examined the differences in sleep medication administration patterns between RNs and LPNs working in skilled nursing facilities.

Hunting Firearm Injuries, North Carolina

THOMAS B. COLE, MD, AND MICHAEL J. PATETTA, MA

Abstract: To determine the percentage of unintentional firearm-related injuries associated with hunting and to identify risk factors, we conducted a retrospective, descriptive survey of all hunting firearm injuries identified by two North Carolina surveillance systems. Almost one-third of unintentional shooting deaths are hunting-related, and young hunters appear to be at greatest risk of injury. Safety instruction and wearing highly visible clothing should be encouraged; controlled studies should test the effectiveness of these preventive measures. (*Am J Public Health* 1988; 78:1585–1586.)

Introduction

Unintentional firearm injuries are a small but significant fraction of all firearm injuries in the United States. Approximately one-fifth of unintentional firearm injuries have been attributed to hunting.[1,2] We retrospectively reviewed all reports of fatal and nonfatal hunting firearm injuries identified by two North Carolina surveillance systems for the two-year period 1984–85 and all fatal hunting firearm injuries for the five-year period 1981–85.

Methods

Data from two sources, Outdoors Accident (OA) Reports of fatal and nonfatal hunting injuries and Medical Examiner (ME) reports of fatal injuries for the years 1984 and 1985, were merged. OA Reports were obtained from the North Carolina Wildlife Resources Commission and ME Reports from the North Carolina Office of the Chief Medical Examiner. ME Reports are required by law to be submitted for all fatal injuries,[1] and are therefore assumed to be population-based. Because ME Reports are not computer coded according to whether the injury was hunting-related, all unintentional firearm deaths were reviewed as well as all intentional firearm deaths with codings that suggested an increased probability of being hunting-related (outdoor non-residential location, non-handgun weapon, or undetermined manner).

A case was defined as a firearm injury for which the shooter was known to be hunting. The period of hunting, as defined on the Outdoors Accident Report form, extends from the time when "hunting equipment is removed from its natural place of storage until it is returned to storage after the hunt."

The number of hunting licenses issued in North Carolina in 1985 and the number of deer reported killed in 1985 (using data obtained from records of big game licenses) were obtained from the North Carolina Wildlife Resources Commission. US Census data from 1980 were used to assign a designation of rural or urban to each county.

All statistical tests are by Fisher exact test, two-tailed. Relative risks are reported with exact 95% confidence intervals.

Address reprint requests to Thomas B. Cole, MD, North Carolina Division of Health Services, Environmental Epidemiology Branch, P.O. Box 2091, Raleigh, NC 27602. Dr. Cole was on assignment there from the Division of Field Services, Epidemiology Program Office, Centers for Disease Control, Atlanta, GA. Mr. Patetta is with the State Center for Health Statistics, North Carolina Division of Health Services, Raleigh, NC. This paper, submitted to the Journal January 28, 1988, was revised and accepted for publication May 3, 1988.

Results

There were 78 fatal and nonfatal hunting firearm injuries in 1984–85. The ratio of injury to hunters was 11.3 per 100,000 hunting licenses sold per year. The ratio of firearm injuries to deer hunters during this period was 34.7 per 100,000 deer killed per year. The rate of hunting firearm injuries for North Carolina residents was 0.6 per 100,000 persons per year.

Of the 78 hunting firearm injuries reported during 1984–85, 22 (28 per cent) were fatal, 30 per cent of all unintentional firearm fatalities in North Carolina during 1984–85. Fatal hunting injuries might account for less than 28 per cent of the total because nonfatal firearm hunting injuries are probably underreported to the Wildlife Resources Commission.

Of all 78 victims injured in 1984–85, 72 (92 per cent) were hunting at the time of injury, and 85 per cent of the injuries occurred during deer hunting season from mid-October to January 1. Most other game can be legally hunted only during the fall and early winter as well. Hunting firearm injuries were reported from 47 of the 100 counties in North Carolina.

Of the 66 shooters whose counties of residence were known, 46 (70 per cent) were hunting in their home county, and 14 (21 per cent) were hunting in a county that bordered on their home county.

The median age of victims injured by hunting firearms in the state in 1984–85 was 25 years. The median age of 68 shooters was 23 years. Of the 10 shooters <15 years of age, five (50 per cent) were hunting without the supervision of an adult (≥21 years old). Of the 12 shooters 15–17 years of age six (50 per cent) were hunting without adult supervision. Seventy-three of 78 victims (94 per cent) and 70 of 70 (100 per cent) shooters whose sex was recorded were male.

All hunting-related injuries reported in 1984–85 were unintentional. The relationship of shooters to victims is described in Table 1. In only 18 cases was the shooter a stranger.

Only 8/67 victims were wearing highly visible (red or orange) clothing when they were shot. Overall, 25/78 (32 per cent) victims were shot under conditions of good visibility, in daylight when the weather was clear in an open area (defined as the absence of woods, underbrush, or tall weeds, crops, or grass between victim and shooter) on level ground.

A narrative description of events was provided for 74/78 cases. From these narratives, 165 unsafe hunting practices were determined to have been committed by shooter or victim or both, for a mean of 2.2 unsafe hunting practices per injury (Table 2). These 165 practices included 22 different types of unsafe hunting practice. In every hunting firearm injury case for

TABLE 2—Number and Percentage of the Five Most Common Types of Unsafe Hunting Practice Reported for 78 Hunting Firearm Injuries, North Carolina, 1984–85

Unsafe Hunting Practices	Number (Percent) (N=103)
Firearm discharged although trigger was said not to be pulled*	32 (31)
Carrying firearm incorrectly**	20 (19)
Victim covered by shooter swinging on game	19 (18)
Victim out of sight of shooter	17 (17)
Victim mistaken for game	15 (15)

*By 8–19-year-olds 17/26 vs ≥ age 20, 15/42. Relative risk 1.8 (95% CI 1.1, 3.0)
**By 8–19-year-olds 14/26 vs ≥ age 20, 6/42. Relative risk 3.8 (95% CI 1.6, 9.8)

which a narrative was provided, there was at least one unsafe hunting practice. Two unsafe hunting practices were more likely to be committed by younger shooters. Fourteen of 61 shooters reported having completed a hunter safety course.

Review of Medical Examiner reports for the five-year period 1981–85 found that blood alcohol tests were performed for 41 of 50 fatal hunting firearm victims. Of these 41, six were positive. Among the 14 victims of self-inflicted injury who were tested for alcohol, five had positive blood alcohol tests, two of which were suicides.

Discussion

Estimates of the percentage of unintentional firearm injuries attributable to hunting in the United States vary.[1–3] Discrepancies could be due to the method used to classify unintentional shootings as being hunting-related. We believe our case-by-case review to be the best approximation of the percentage of unintentional firearm fatalities associated with hunting which has been published to date.

Most shooters and victims in this study were young, and half of the child and adolescent shooters were hunting without adult supervision. By contrast, 60 per cent of victims of fatal hunting firearm injury in a Swedish study were 40 years of age or older.[4] The probable explanation for this difference in age is that Swedish children do not hunt; in Sweden only airguns can be legally owned or used by persons under the age of 18.

North Carolina law prohibits the use of firearms by children <12 years old unless they are accompanied by an adult. In this series of hunting firearm injuries, only two shooters were <12 years old: one was supervised by an adult and the other was not. However, 26 shooters, half of whom were unsupervised, were <20 years of age. Adult supervision of child and adolescent hunters, particularly those who have not had formal instruction in the safe use of firearms, might prevent many hunting firearm injuries.

Thirty-nine states including North Carolina require hunters to wear fluorescent orange clothing while hunting to increase their visibility to other hunters; fluorescent orange clothing was not required for hunters during the periods of this study, however. Clothing of this color has been shown to be more visible to the human eye, particularly in low-light conditions, than clothing of other colors.[5] Without knowing how many hunters who were not injured by firearms in 1984–85 were wearing fluorescent orange clothing, we could not determine whether wearing fluorescent orange was statistically associated with a decreased risk of hunting firearm injury.

Smokeless Tobacco Use and Attitudes toward Smokeless Tobacco among Native Americans and Other Adolescents in the Northwest

ROBERTA L. HALL, PHD, AND DON DEXTER, DMD

Abstract: A survey of 1,180 sixth, ninth, and eleventh graders in three school districts in the State of Washington found that 34 per cent of male Native Americans, 24 per cent of female Native Americans, 20 per cent of male non-natives and 4 per cent of female non-natives are current users of smokeless tobacco products. In all areas and groups, the best predictor of whether an adolescent is a user is the use pattern of friends. (*Am J Public Health* 1988; 78:1586–1588.)

Introduction

Smokeless tobacco in the form of chewing tobacco and snuff is a highly addictive substance that poses many health hazards for the growing number of children and adolescents who use it.[1–4] Nicotine and other harmful chemicals in tobacco are absorbed into the user's body through the mucosa. Oral leukoplakia, a white thickening of the oral mucosa, is a common consequence of use and is considered a precancer indicator.

Many studies have reported a growing use of smokeless tobacco in the general population[5,6] but only a few have focused on Native Americans. Schlife[7] in a study of 2,454 girls and 2,511 native and non-native boys in rural Alaska ages 5 to 18 found that 28 per cent of the girls and 34 per cent of the boys used smokeless tobacco products. In a study of 144 Native Americans, grades kindergarten through 12 from Alaska and Washington, Schinke, *et al*,[8] found that 19 per

cent of the females and 42 per cent of the males had used smokeless tobacco at least 20 times.

Methods

To investigate risk factors predictive of smokeless tobacco in native populations and to determine attitudes that suggest mechanisms for intervention, the Northwest Portland Area Indian Health Board contracted with staff at Oregon State University for a survey of school-aged youth. Three Washington State school districts where Native American youth comprise a significant minority were chosen to represent the geographic diversity of the Northwest. Neah Bay is a small, isolated community at the extreme northwestern tip of the state; Colville is a large, isolated reservation in the center of the state; and the third district lies adjacent to the Lummi Reservation near Bellingham in the urbanized western sector. In 14 schools in these areas, all sixth, ninth, and eleventh graders at school on the day of the survey in May 1987 were asked to participate. The refusal rate was 3 per cent and the absentee rate was 13 per cent. A total of 1,180 took part.

The survey ascertained respondents' use, individual traits (such as age, sex, and tribe), use practices of family and friends, and attitudes. Respondents who said they had never used smokeless tobacco were defined as non-users (640 or 54 per cent); those who currently use smokeless products constituted the users category (197 or 17 per cent); those who reported they had used but no longer used the product were categorized as former users (343 or 29 per cent). Comparisons were made between use categories and age, sex, Indian status, grade, area, attitudes, and use by friends and relatives. Multiple regression models were developed to test predictive models of use status and frequency of use.

Results

Use of smokeless tobacco products varies by ethnic status, sex, and, to a lesser extent, by grade level (Table 1), but these factors interact. Native American use in all areas is higher than non-native use. The contrast is particularly striking among females: whereas only 4 per cent of the non-native female sample use smokeless products, 24 per cent of Native American females are users.

The Native American sample is characterized by a younger age at first use; 33 per cent of native former users and 57 per cent of users tried smokeless tobacco before the age of 10 while only 17 per cent of non-native former users and 24 per cent of users had done so.* A larger percentage of non-users (80 per cent) had never smoked cigarettes than former users (49 per cent) or users (42 per cent).

Multiple regression was used to test a model of variables predicting whether a person is a user, former user, or non-user of smokeless tobacco with separate tests for males and females. Variables included age, grade in school, Native American or non-native ancestry, proportion of friends who use smokeless tobacco, smoking of cigarettes, and use by siblings, fathers, mothers, and other relatives. For boys, the model produced an adjusted R^2 of 0.4593. The number of friends who use the product contributed the greatest portion of the variance explained; other explanatory variables included: having smoked cigarettes, use by siblings, use by other relatives, and use by the father (see Table 2). In females the most important variable also was friends' use but include native ethnicity, grade in school (negatively related to use of smokeless tobacco), and age (positively related) in addition to variables found in the male model. The adjusted R^2 is 0.3935.

Regression models with the same variables were developed to predict the frequency and quantity of use but were less successful, in part due to smaller sample size. The only important variables for boys were friends' use and age at first use (adjusted R^2=0.2329); for girls it was friends' use (adjusted R^2=0.1619).

Attitudes toward smokeless tobacco vary significantly among users, former users, and non-users, but not at all by sex, ethnic group, area, or age. Reasons given for starting to use and continuing to use smokeless tobacco related to pleasure and taste with fewer than 10 per cent indicating peer pressure or addiction. Principal reasons non-users gave for not trying it focused on health issues and the unpleasant smell and appearance of smokeless products.*

Discussion

Although the rate of use of smokeless tobacco varies greatly by area, sex, and ethnic status, the pattern of attitudes held by users cross-cuts other differences. Included in the

TABLE 1—Use of Smokeless Tobacco, in Percentages, by Area, Ethnic Group, Grade, and Sex

Category	(N)	Category of Use: Non-User	Former User	Current User
Grade Level				
6	(379)	69	21	10
9	(428)	45	33	21
11	(373)	49	32	18
Area and Ethnic Group*				
Colville Native American	(128)	21	31	44
Colville non-native	(315)	57	34	9
Bellingham Native American	(92)	47	33	20
Bellingham non-native	(529)	63	23	14

Age	−.002	.036	.108	.038
Grade in school	.039	.038	−.122	.039

*Data available on request to author.

pattern is a denial of the role of peer pressure even though friends' use is the most important predictor, and denial of addiction, even though in both sexes and ethnic groups and in all three areas over half of the users said they "would quit if they could." These data suggest that intervention programs need to work with issues of friendships, pleasure, appearance, and health, and suggest that some adolescent users would respond positively to cessation programs if they were available.

ACKNOWLEDGMENTS

The project was funded by an Indian Health Service grant (contract no. 248-87-0037) made to the Northwest Portland Area Health Board, 520 SW Harrison, Suite 440, Portland, OR 97201. A full report has been provided to the Indian Health Service. During 1988, the findings were presented at the Northwest Anthropology meetings in Tacoma in March, to meetings of the Indian Health Board in April, and at meetings of the US Public Health Service in May.

NIH Consensus Statement Available on Perioperative Red Cell Transfusion

Transfusion of red cells is a life-saving measure in the management of a variety of medical and surgical conditions. The AIDS epidemic has recently raised the level of apprehension regarding the transmission of infectious disease by blood transfusion. Furthermore, there is new information about the significance of anemia in the perioperative period. These developments have stimulated a reexamination of the benefit-to-risk relationship for transfusion therapy.

To assess this procedure, the National Institutes of Health held a Consensus Development Conference on Perioperative Red Cell Transfusion, June 27–29, 1988. Based on scientific data presented, a consensus panel, drawn from the medical profession, blood blanking organizations, and the general public wrote a consensus statement. Following is a brief suramary of the panel findings:

- A hemoglobin of less than 10 g/dL or a hematocrit of less than 30 per cent indicates a need for perioperative red cell transfusion.
- Most patients with hemoglobin values >10 g/dL rarely need perioperative transfusions, whereas those with acute anemia and hemoglobin values <7 2/dL will more frequently need blood.
- Deciding to transfuse red cells depends on clinical assessment aided by laboratory data such as: arterial oxygenation, mixed venous oxygen tension, cardiac output, the oxygen extraction ratio, and blood volume, when indicated.
- There is no evidence that mild to moderate anemia contributed to perioperative morbidity.
- The number of homologous transfusions should be kept to a minimum.
- Although homologous red cell transfusions are becoming safer, they should not be considered substitutes for good surgical and anesthetic techniques.
- A variety of alternatives to homologous transfusions now are available, including the use of autologous blood, collected perioperatively, and by intraoperative blood salvage, which appears to be safe in some applications.

Free, single copies of the complete *NIH Consensus Statement on Perioperative Red Cell Transfusion* may be obtained from the Office of Medical Applications of Research, Building 1, Room 216, National Institutes of Health, 9000 Rockville Pike, Bethesda, MD 20892.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health*, 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5668 or 5600. All advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. Potential for Exposure to Tick Bites in Recreational Parks in a Lyme Disease Endemic Area

RICHARD C. FALCO, PHD, AND DURLAND FISH, PHD

Abstract: Eight recreational parks located in a Lyme disease endemic area of southern New York State were surveyed for the presence of ticks during the summer of 1985 by drag sampling. *Ixodes dammini*, the primary vector of Lyme disease in the northeast, was found in all but one park and accounted for 580 (91.8 per cent) of the 632 ticks collected. Of these, 18 per cent were larvae, 80 per cent were nymphs, and 2 per cent were adults.

An *I. dammini* encounter distance, defined as the mean number of meters traveled before encountering a nymphal or adult *I. dammini* on a drag cloth, ranged from 36 m in high-risk parks, to infinity (no tick encounters). Generally, areas of high use presented higher encounter distances (lower risk) than those of the entire park. Two of the three parks with the highest annual attendance also had the highest *I. dammini* population indices as projected from our sampling regimen. These results indicate that recreational parks in Lyme disease endemic areas represent a substantial human risk for tick bites and Lyme disease. (*Am J Public Health* 1989; 79: 12–15.)

Introduction

Lyme disease is a potentially serious tick-borne spirochetosis with a world-wide distribution.[1] It is particularly prevalent in the northeastern United States, where the deer tick, *Ixodes dammini*, is the primary vector.[2,3] Westchester County, New York, located to the immediate north of New York City, is an endemic area for Lyme disease,[4] and has an abundance of recreational parks, campgrounds, and nature preserves.

Lyme disease can be difficult to diagnose,[5] and delayed treatment may lead to cardiac and neurologic abnormalities,[6,7] as well as chronic arthritis.[8] Because of this potential for serious sequelae, early recognition and treatment of Lyme disease is important. Preventing the infection is preferable, but this requires knowledge of tick infested areas in order that tick bites may be avoided. Also, because many Lyme disease patients do not recall receiving a tick bite,[9] knowledge of exposure to infested areas may be helpful in diagnosing the disease.

The presence of homophilic ticks in recreational areas can constitute a significant public health threat.[10] For example, 45 cases of tick-borne relapsing fever were reported to have been acquired at Grand Canyon National Park during a single outbreak in 1973.[11] A recreational area in Tennessee, where serologic evidence from mammals and pathogen isolations from ticks showed Rocky Mountain spotted fever and tularemia to be endemic,[12] was found to have an abundance of the vector species *Amblyomma americanum* and *Dermacentor variabilis*.[13]

Commonly used methods for sampling ticks include the use of carbon dioxide-baited tick traps,[14] examination of host animals,[15] and drag sampling.[16] Although recreational areas elsewhere have been sampled for other tick species,[11,13] there is no published regimen to efficiently sample recreational parks for the presence of *I. dammini* in Lyme disease endemic areas.

In order to identify recreational areas with potential for subjecting the public to risk of acquiring tick bites, and possibly Lyme disease, a project was begun in 1985 to design an efficient sampling regimen to assess the species and abundance of ticks of public health importance in parks operated by the Westchester County, New York, Department of Parks, Recreation, and Conservation.

Methods

Eight recreational parks operated by the Westchester County, New York, Department of Parks, Recreation, and Conservation were selected for this study. Selected parks attracted large numbers of summer visitors and/or were located near clusters of Lyme disease cases reported to the Westchester County Department of Health. Sampling was performed in 1985 during the months of June and July when the nymphal stage of *I. dammini*, which is responsible for the majority of Lyme disease cases, is most active.[4,17] These months are believed to represent the greatest period of public exposure to Lyme disease.

Because the nymphal activity peak spans a narrow range of time, an efficient sampling regimen was required. Drag sampling provides information for a greater land area per unit effort than does either animal trapping or carbon dioxide-baited tick traps. Therefore, all parks were surveyed for ticks by drag sampling. This method involved dragging a one square meter flannel cloth, fixed to a wooden handle, over substrate and vegetation through the parks.[16] The cloth was examined every 20 meters for the presence of ticks, which were collected and preserved in alcohol for later identification. Because ticks captured by this method were seeking hosts, they represent the portion of the resident tick population that presents a risk for humans.

Transects were established through each park in order to systematically sample ticks from all habitats. Each transect consisted of a straight line through the park extending from border to border. To avoid sampling bias caused by vegetation or topography, orientation of the transects was in north-south and/or east-west directions. Because sampling time was limited, the objective was to sample as close to 1 per cent of the park as possible without spending more than five man-days at any one park. The number of transects sampled at each park therefore varied from one to five, with a mean of 3.9 (SD=1.45). Total sampling time was recorded for all areas.

In addition to the transects, areas of high public usage were designated by Westchester County Department of Parks, Recreation, and Conservation personnel to be included in the survey. As in the transects, these locations were sampled by drag sampling. High usage areas included wooded and grassy areas, as well as trails and developed land. Such areas were designated for all parks except one, which was not open to the public during the sampling period.

An "encounter distance" for *I. dammini* was determined for each park in order to compare relative risk among parks. Defined as the mean number of meters traveled before encountering a nymphal or adult *I. dammini* on the drag cloth, an encounter distance was calculated as the reciprocal of the mean number of ticks collected per linear distance sampled. This distance has an inverse relationship to risk since parks with lower encounter distances have a greater likelihood of a person encountering a tick. Encounter distances were based on nymphs and adults only, as larvae are not considered to be epidemiologically important vectors of Lyme disease.[18,19]

The potential public health hazard from exposure to *I. dammini* in each recreational park was estimated by comparing the 1984 park attendance figures provided by the Westchester County Department of Parks, Recreation, and Conservation, to an *I. dammini* population index. This index was based on the number of nymphal and adult *I. dammini* found in the areas sampled extrapolated to the total area of the park. Park attendance figures were not available for two of the parks sampled.

Results

A total of 632 ticks, representing five species, were collected during this study (Table 1). The most abundant species was *I. dammini* (91.8 per cent) and it was found in all parks but one. Of the 580 total *I. dammini* collected, 105 (18.1 per cent) were larvae, 463 (79.8 per cent) were nymphs, and 12 (2.1 per cent) were adults (nine males, and three females). *D. variabilis* was the second most common species (5.5 per cent), and was found in all but two parks. *I. dentatus* (1.6 per cent), *Haemophysalis leporispalustris* (0.9 per cent), and *I. cookei* (0.2 per cent) were also collected.

Sampling time totaled 173.3 man hours and ranged from 6 hrs 20 mins to 35 hrs 10 mins per park, with a mean of 21 hrs 40 mins (Table 2). This effort resulted in less than 1 per cent of the total land area for each park being sampled. Sampling time was dependent upon density of vegetation and number of immature ticks collected. A mean of 11 minutes was required per 100 meters sampled. However, sampling time for particular transects and high use areas ranged from two to 25 minutes per 100 meters.

Calculated *I. dammini* encounter distances for the total sampling area at each park ranged from 36 m to infinity, where no *I. dammini* was found (Table 3). A comparison of the encounter distances for the eight parks sampled in this study reveals two distinct groups: high-risk and low-risk parks. High-risk parks had relatively low encounter distances of 36 m, 38 m, 88 m, and 118 m (Table 3). Low-risk parks had encounter distances of 208 m, 303 m, 3,333 m and infinity. The lowest encounter distance in this group is almost double that of the highest in the high-risk group. The extremely high encounter distances of 3,333 m and infinity suggest that there is little or no chance of encountering *I. dammini* at these parks.

I. dammini encounter distances for the high use areas alone (Table 3) were, in most cases, higher than those determined for the entire parks. In only two parks were the encounter distances lower in the high use areas. Total area encounter distances were 3,333 m and 118 m at these parks, while encounter distances for the high use areas were 2,000 m and 112 m, respectively.

The total public health risk from ticks in these recreational parks, based upon their attendance figures and *I. dammini* population indices, is shown in Table 4. Of the three parks with the highest attendance figures, two also yielded the highest *I. dammini* population indices. This suggests a greater potential for public exposure to tick bites at these parks.

Discussion

The large number of *I. dammini* collected suggests that it is the most abundant tick species encountered by humans

in Westchester County parks. This finding alone implies that there is some risk of being bitten by *I. dammini* and of acquiring Lyme disease in seven of the eight parks sampled. Risk for Lyme disease is further implied by a previous study which detected spirochetes in 49.1 per cent of the nymphs and 53.6 per cent of the female *I. dammini* in Westchester County.[20]

The encounter distance used to quantify risk in this study is a more precise measure of risk for acquiring tick bites than is the total number of *I. dammini* collected in each park. Because the area of recreational parks may vary and sampling time may be restricted, it is difficult to achieve equal sampling effort at all sites. The encounter distance provides an index of tick abundance that allows for wide differences in total sampling effort.

The relatively higher encounter distances in the high use areas indicate that, for most parks, there is less risk of *I. dammini* bites in areas which are heavily used by the public. Fewer ticks in high use areas may be due to habitat alteration, such as buildings, roads, and maintained lawns which may discourage mammalian hosts or decrease tick survival. In studies of the lone star tick, *Amblyomma americanum*, areas with maintained vegetation have been found to have fewer ticks than wooded habitats.[21] Carey, *et al*,[22] found *I. dammini* more abundant in wooded than open areas. However, other studies have also determined that *I. dammini* may be prevalent in well maintained lawns.[23] Finding fewer ticks in high use areas could result from ticks attaching to humans and being removed from the host-seeking population.

The total public health risk from recreational activities in these parks may be significant (Table 4). For example, one park had both the highest patronage (151,131) and the highest *I. dammini* population index (146,401). With an *I. dammini* encounter distance of only 118 m, this park constitutes the greatest risk for tick exposure of all the parks studied. A similar situation existed at the park which had the lowest *I. dammini* encounter distance (36 m), and the third greatest park attendance (44,675).

In contrast to these extremes were the parks where the encounter distance were 3,333 m and infinity. Although the former had the second greatest number of patrons (84,606), it had a relatively low *I. dammini* population index (584). In the other, no *I. dammini* were found at all. Risk of exposure to *I. dammini* at these two parks is lowest of all those surveyed.

The presence of *I. dentatus* and *H. leporispalustris* in parks is not considered to be a public health threat. These species are not known to transmit Lyme disease or other illnesses to humans and they do not readily bite humans.[24] However, the presence of *I. cookei* may have public health significance as this species has been shown to be infected with Powassan encephalitis virus in the northeast[25] and is known to bite humans.[26,27]

The presence of *D. variabilis* in six of the eight parks sampled may also be significant because of this tick's role as the primary vector of Rocky Mountain spotted fever in New York State.[28] However, *D. variabilis* is much less common than *I. dammini* in this area,[24] and the incidence of Rocky Mountain spotted fever in this region is low.

Drag sampling is an efficient method for sampling *I. dammini* in large public recreational areas. It is a common tick collecting method[16,26,29,30] and has been applied in studies of Rocky Mountain spotted fever,[12,13,28,31] tularemia,[12,13] and Lyme disease.[20,23] To our knowledge, however, there is no previously published study describing a regimen suitable for quantitative sampling of nymphal *I. dammini* in large recreational areas.

Despite the efficiency of our sampling design, less than 1 per cent of each park was sampled for ticks. However, a mean of 21 hrs 40 mins spent at each park indicates that a surveillance project such as this requires considerable labor.

Unfortunately, practical methods to control *I. dammini* in areas the size of large recreational parks have not been developed. To reduce the incidence of Lyme disease in endemic areas, public health efforts should therefore be focused on identifying areas that present a high risk for acquiring tick bites. The public can then be educated to avoid tick infested areas and in ways to prevent ticks from biting. Educational efforts should include the posting of affected areas and the distribution of literature discussing the risk and prevention of tick bites and the symptoms of Lyme disease. We have demonstrated that public recreational parks should be an important target for this effort.

ACKNOWLEDGMENTS

The authors thank Karl Schoeberl and Luis Ruedas of the Westchester County Department of Health for their assistance with the field work, Dr. Thomas Daniels of the New York Medical College Medical Entomology Laboratory for comments on the manuscript, and the administrators and personnel of the Westchester County Department of Parks, Recreation, and Conservation for their cooperation. This research was conducted by R. Falco as partial fulfillment of the PhD degree in Biology at Fordham University and was funded in part by the Westchester County Department of Health, the Fordham University Research Council, and two anonymous donors. Portions of the findings were presented at a conference for local health professionals, May 18, 1988, sponsored by the Westchester County Department of Health and the New York Medical College.

New Osteoporosis Bibliographies Available

Osteoporosis is the topic of two new bibliographies available from the National Arthritis and Musculoskeletal and Skin Diseases Information Clearinghouse of the National Institutes of Health.

Osteoporosis affects an estimated 24 million Americans and is a major underlying cause of bone fractures in post-menopausal women and older persons in general. These bibliographies provide access to educational materials for patients and health professionals.

The bibliographies contain a total of 186 citations of patient and professional materials, most of them published since 1983. Each citation includes an abstract; information on the source of the material, its availability, and price; and, when applicable, the number of references cited in the article.

- The bibliography of *patient education materials* contains 37 citations. Public awareness of the problems caused by osteoporosis has risen considerably in recent years and women of all ages seek information on how to prevent or at least delay the onset of osteoporosis. In response to this rising awareness and expressed need, organizations have produced many brochures, pamphlets, audiovisuals, and other materials aimed at the patient and general public. These references are included in this bibliography. Healthy professionals and health educators may find this bibliography useful in selecting specific education materials to enhance patient teaching and counseling. Many of the materials are available at no charge.
- The bibliography of *professional education materials* contains 159 annotated citations; they provide physicians, nurses, and other health professionals with information on journal articles, books, audiovisuals, and other continuing education materials regarding the diagnosis, prevention, treatment, and epidemiology of osteoporosis. Both author index and title index are provided.

To obtain these bibliographies, send a check payable to AMS Clearinghouse ($2.00 for Patient Education, $4.00 for Professional Education) to: NAMSIC, Box AMS, Bethesda, MD 20892.

Frequency of Worksite Health Promotion Activities

JONATHAN E. FIELDING, MD, MPH, AND PHILIP V. PISERCHIA, MS

Abstract: The first National Survey of Worksite Health Promotion Activities surveyed a random sample of all private sector worksites with 50 or more employees, stratified by number of employers, geographic location, and type of industry. The 1,358 completed interviews constituted a response rate of 83.1 per cent. Of responding worksites 65.5 per cent had one or more areas of health promotion activity with slightly more than 50 per cent of activities initiated within the previous five years. Overall prevalence by type of activity included health risk assessment (29.5 per cent), smoking cessation (35.6 per cent), blood pressure control and treatment (16.5 per cent), exercise/fitness (22.1 per cent), weight control (14.7 per cent), nutrition education (16.8 per cent), stress management (26.6 per cent), back problem prevention and care (28.5 per cent), and off-the-job accident prevention (19.8 per cent). Mean number of activities across all worksites was 2.1 and for worksites with activities, 3.2. Activity frequency increased with worksite size, was highest in the western region (2.34) and lowest in the northeast (1.96), and varied considerably by industry type. The majority of worksites paid the entire cost of these activities. (*Am J Public Health* 1989; 79: 16–20.)

Introduction

The worksite has been identified as an appropriate target for health promotion activities. Rationales for the workplace as an advantageous site for the efficient delivery of health promotion include: the large amount of time spent there by the majority of the population, the economic and other incentives for employers to invest in employee health promotion, the opportunity to mobilize peer pressure to help employees make desirable changes in health habits, as well as increasing reports of implementation of risk factor reduction at the worksite and some reports of program success.[1–11]

Response rates varied greatly in the three industry-specific[12–14] and six statewide surveys of health promotion activities performed between 1978 and 1986[15–20] and one survey (Colorado) included in their denominator only those worksites with an ongoing activity or planned programs. The reported percentage of worksites with at least one health promotion activity ranged from 17 per cent to 78 per cent. Surveys generally covered hypertension control, smoking cessation, weight control, nutrition, exercise/fitness, stress management and sometimes covered accident prevention, cancer risk reduction, mental health counseling, drug abuse education/referral, and cardiopulmonary resuscitation (CPR). In each survey, the prevalence of any activity and of most specific types of activities increased with worksite size. The results of one survey (California) supported the premise that employers are adopting these activities at an accelerating rate. This paper presents results of the first systematic nationwide assessment of worksite health promotion activities, including descriptive data on worksites surveyed, the employee population, and the frequency and nature of the activities.

Methods

The target population was all worksites in the private sector in the United States with 50 or more employees. The 1984 Dun and Bradstreet listing of private corporation worksites was used to identify a sample of worksites representative with respect to employee size, geographic location, and type of industry. The employee size reported by the worksite (which often differed from the size in the Dun and Bradstreet listing) was used for analysis and reporting purposes. Worksites identified as having 50 or more employees in the Dun and Bradstreet listing but reporting fewer than 50 employees were retained in the sample.

A sample of worksites was selected in each of two size categories. In the first category (50–99 employees), 600 worksites were selected with equal probability and allocated proportionally to the number of worksites in the universe in each of 24 classes defined by geographic region (four classes) and type of industry (six classes). In the second category (100 or more employees), 3,000 worksites were selected with equal probability and allocated proportionally to the number of worksites in the universe in each of 72 classes defined by geographic region (four classes), size of worksite (three classes), and type of industry (six classes). The sample selection used the Probability Minimum Replacement Method.[21]

Each sample site was randomly assigned to an interview list so that each list constituted a valid probability sample. Telephone interviews were conducted until a sufficient number of completed interviews was achieved to give coefficients of variation of about 5 per cent for the natural prevalence estimates. Once a list was begun, all the worksites on that list were contacted to ensure a valid probability sample. The 1,700 (Table 1) worksites in the final sample led to 1,358 completed interviews (320 for the employee size 50–99, and 1,038 for employee size ≥100).

Sampling weights were equal within each of the two size categories but, to avoid bias from nonresponse, the sampling weights of the respondents were adjusted so that their sum was equal to the number of worksites in the survey population. Because the sample of worksites was not a simple random sample and ratio adjustments were applied to the sample weights, special computer software was used for the computation of frequencies[22] and means.[23]

The instrument consisted of six sections. The introductory section confirmed that the appropriate worksite had been contacted, that the most appropriate person was being interviewed, and established the extent to which the employer, union, and employee group were providing financing and/or logistical support for these activities. The respondents at each worksite were queried about the demographic characteristics of the workforce, their own position and job respon-

sibilities, and the presence of nine types of health promotion activities: health risk assessment, smoking cessation, blood pressure screening and treatment, exercise and physical fitness, weight control, nutrition education, stress management, back problem prevention and care, and off-the-job accident prevention. Worksites with at least one type of activity were asked to distinguish between passive activities, such as policy or information, and active employee participation, and to characterize the latter types, if present.

A lead letter to worksites introduced the survey and was followed by a computer-assisted telephone interview (CATI) with the person identified by that worksite as most familiar with its health promotion activities. Survey questions were displayed for the interviewer in program-controlled sequences on computer terminals, and responses were entered directly into the computer. The computer automatically performed checks for valid codes, consistency, and completeness.

There were 1,358 completed interviews, a response rate of 83.1 per cent (Table 1). The remaining 16.9 per cent included worksites which refused to participate, gave only partial data, could not be located, or were out of business. To complete an interview small worksites averaged three contacts and large worksites, four. Average interview time was 30 minutes.

Data analysis included frequencies and means, with frequency estimates of the universe obtained using RTIFREQS[22] and means using SESUDAAN,[23] both accessed through SAS software.[24]

Results

Worksites

Dun and Bradstreet data tended to overstate worksite size compared to worksite report. As a result, 137 of worksites reported having fewer than 50 employees despite contrary information in the sampling database. All surveyed worksites are included in the final sample to reflect the total universe based upon the original sampling frame. However, as worksites with fewer than 50 employees were not intentionally sampled, results for the 1–99 employee worksites cannot be generalized to the universe of worksites of that size.

Stratifying variables and frequencies based on worksite responses are displayed in Table 2. Although worksite size is an explanatory factor in the occurrence of all types of health promotion activities, unadjusted prevalences are used to accurately present baseline data by geographic region and industry type.

Workforce

Full-time employees (working 35 hours or more per week) made up over three-fourths of the workforce at 73 per cent (SE 1.4) of the worksites. Only 13.1 per cent (SE 1.1) of all worksites reported having no blue collar employees. The blue collar percentage of the population tended to decrease with increasing worksite size, with little regional variation.

Some union representation was reported by 25.5 per cent (SE 1.4) of worksites, with frequency varying directly with worksite size. A majority of represented employees was most frequent in the northeast United States (27.4 per cent SE 3.3). The percentage of blue collar workers, male workers, workers less than age 30, and workers represented by a union did not affect probability of a worksite having one or more health promotion activities.

Slightly more than one-half (51.6 per cent SE 2.3) of reported health promotion activities were initiated during the previous five years and 11.3 per cent (SE 1.6) within the prior 12 months. Longer duration activities included those in place 6–10 years (17.6 per cent SE 2.1), 11–20 years (10.4 per cent SE 1.3), and more than 20 years (8.6 per cent SE 1.4).

Health Promotion Activities

At least one type of health promotion activity was reported by 65.5 per cent (SE 1.7) of all worksites surveyed, with 2.1 (SE 0.1) activities per worksite for all responding worksites versus 3.3 (SE 0.1) for worksites with activities. For all worksites means increased from 1.37 (SE 0.1) in the smallest size (<100) to 4.64 (SE 0.3) in worksites with 750 or more employees. Interregional activity ranged from 1.96 (SE 0.2) (northeast region) to 2.34 (SE 0.2) (western region), considerably less than across industry type ranging from 1.47 (SE 0.2) in the "Other" category (Table 2) to 2.64 (SE 0.3) in the "Utilities Transportation Communications industry" (UTC).

The overall and worksite size specific prevalence rates for the nine activity types are shown in Table 2. For each, frequency increased with worksite size. Worksites with 750+ employees had an overall activity frequency of 87.6 per cent (SE 3.9), 1.6 times that of worksites with fewer than 100 employees, which was 55.5 per cent (SE 2.8). Frequency differences between the largest size (750+) and the next largest size (250–749) groups were generally greater than between the three smaller size groupings for each activity type. Frequency differences were small among regions but more pronounced among industries, and rank order by industry varied considerably by activity type.

Of all worksites, 29.5 per cent (SE 1.4) had some type of health risk assessment (HRA) activity. Health risk assessment activities were defined as any activity designed to measure employee health status or health risk, such as health risk appraisal, health examinations, physicals, or screenings. Periodic health or physical examination was available at 77.4 per cent (SE 2.3)* of these worksites and included blood pressure screening, 55.4 per cent (SE 3.1); tests of physical fitness, 15.0 per cent (SE 2.5); cancer screening, 19.5 per cent (SE 2.2); and blood tests for cholesterol, 28.3 per cent (SE 2.8) or sugar, 39.0 per cent (SE 2.8). A health risk assessment questionnaire was available at 24.0 per cent (SE 2.4) of all

*Frequencies for each specific activity are reported as a per cent of worksites with each type of activity.

TABLE 2—Frequency of Health Promotion Activities by Stratifying Variables [Prevalence in Per Cent and Standard Error (SE)]

worksites with HRA activity, but at only 2.9 per cent (SE 0.15) of UTC worksites. None of the "Financial/Real Estate/Insurance" (FRI) or "Other" (OTH) worksites reported mammography screening.

Smoking cessation, the most prevalent activity present in 35.6 per cent (SE 1.5) of all worksites, included formal policies restricting smoking, 76.5 per cent (SE 2.4); information, 54.3 per cent (SE 2.8); classes or workshops, 17.5 per cent (SE 2.4); directly sponsored and self-help cessation materials, 49.7 per cent (SE 2.6). Formal policies restricting smoking were most prevalent at worksites with <100 employees, 84,6 per cent (SE 3.6) and in the "services" (serv) category, 81.8 per cent (SE 3.2). Participatory activities were individual counseling, 15.1 per cent (SE 2.0), group classes or workshops, 19.9 per cent (SE 1.8), and special events or innovations, 23.7 per cent (SE 2.4).

A 16.5 per cent (SE 1.1) prevalence was reported for high blood pressure control activities, ranging from 8.8 per cent (SE 1.7) at worksites with <100 employees, to 48.8 per cent (SE 5.8) at worksites of 750+ employees. Information was provided by 90.7 per cent (SE 2.1), treatment by 23.1 per cent (SE 2.8), referral to an outside physician for treatment by 63.3 per cent (SE 3.6), and special events or innovations by 26.2 per cent (SE 2.9).

Exercise and physical fitness activities were found at 22.1 per cent (SE 1.2) of all worksites surveyed, ranging from 14.7 per cent (SE 1.8) at smaller companies (<100) to 53.4 per cent (SE 5.6) at larger companies (750+). Of worksites with exercise fitness activities, 64.8 per cent (SE 3.0) provided information, 24.9 per cent (SE 2.54) individual counseling, 58.9 per cent (SE 3.5) sponsored group classes or workshops, 26.5 per cent (SE 2.9) subsidized health club membership, 25.4 per cent (SE 2.7) held special events, and 21.5 per cent (SE 2.6) had on-site exercise facilities or equipment for employee use. Worksites with 100–249 employees had the second highest frequency of providing subsidized membership to health clubs (29.9 per cent, SE 4.9) but the lowest frequency of exercise facilities or equipment available at the worksite (13.4 per cent, SE 2.9).

Weight control activities were reported by 14.7 per cent (SE 1.2) of worksites ranging from 8.6 per cent (SE 1.7) (<100 employees) to 47.9 per cent (SE 5.8) (750+ employees). Of these, information was provided by 76.8 per cent (SE 2.9) and self-help materials by 61.5 per cent (SE 3.9). Participatory activities included individual counseling by 42.9 per cent (SE 4.0), group classes or workshops, 51.4 per cent (SE 4.4), follow-up, 48.5 per cent (SE 4.8), and special events 23.0 per cent (SE 3.5). Individual counseling was most common in MAN at 48.2 per cent (SE 8.4) and "service" (Serv) categories at 50.7 per cent (SE 5.3), and group class/workshops

most frequent by far in FRI at 90.4 per cent (SE 6.3). Frequency of follow-up programs by industry type ranged from 50.8 per cent (SE 8.4) in MAN to 17.5 per cent (SE 13.2) in UTC.

The overall frequency for nutrition education activities was 16.8 per cent (SE 1.3) ranging from 9.3 per cent (SE 1.7) at the smaller firms (<100 employees) to 47.7 per cent (SE 4.9) at the larger firms (750+ employees), including information, 89.2 per cent (SE 2.6); group classes or workshops, 42.2 per cent (SE 3.7); individual counseling, 33.3 per cent (SE 3.1); and special events or innovations, 22.8 per cent (SE 2.9). Of worksites with a food service, healthy cafeteria food choices were provided at 51.3 per cent (SE 3.8); of worksites with vending machines, 33.7 per cent (SE 3.3) provided healthy choices.

Stress management activities were found at 26.6 per cent (SE 1.2) of all worksites, ranging from 15.1 per cent (SE 1.7) (<100 employees) to 59.6 per cent (SE 5.3) (750+ employees), with increasing frequency as worksite size increased. Activities included information, 80.7 per cent of worksites (SE 2.7); individual counseling, 39.3 per cent (SE 3.0); group classes or workshops, 58.1 per cent (SE 2.5); follow-up activities, 25.3 per cent (SE 3.5); and special events, 11.5 per cent (SE 1.6). Over 80 per cent reported organizational changes to reduce stress and two-thirds provided special places to relax. The north central region had the highest prevalence for most categories of stress management activity.

Activities to prevent and care for back problems were reported at 28.5 per cent (SE 1.2) of all worksites, ranging from 19.2 per cent (SE 2.0) (<100 employees) to 46.4 per cent (SE 5.3) (750+ employees), including information, 91.4 per cent (SE 1.7); group classes or workshops, 55.5 per cent (SE 3.0); and special events or innovations, 19.7 per cent (SE 2.1).

Almost 20 per cent (SE 1.3) of all worksites had off-the-job accident prevention activities, ranging from 12.8 per cent (SE 1.6) (<100 employees) to 36.8 per cent (SE 5.8) (750+ employees) directed at auto, home, and/or recreational injuries. Information was available at 75 per cent (SE 3.2) of the worksites, group classes or workshops at 27.8 per cent (SE 3.2), and special events at 24.1 per cent (SE 2.8). A formal seat belt policy was in effect at 61.5 per cent (SE 3.4) of worksites.

For nine types of activities surveyed, most companies in all size, region, and industry strata paid the full cost of all activities, including individual counseling at 69.9 per cent (SE 3.1), group counseling or workshops at 76.9 per cent (SE 1.9), and screening at 87.4 per cent (SE 1.9).

At 85.4 per cent (SE 1.9) of worksites with participation activities, all permanent employees were eligible, with a consistent pattern for all stratifying variables. The highest frequency of limiting eligibility to top management or executives was in FRI, at 15.8 per cent (SE 6.9), even though all permanent employees were eligible at 76.8 per cent (SE 7.6) of those worksites.

Coordination of health promotion activities was exclusively in-house at 41.8 per cent (SE 2.7), both inside and outside at 36.3 per cent (SE 2.1), mostly in-house at 14.1 per cent (SE 1.4), mostly outside at 1.7 per cent (SE 0.6), and exclusively outside at 5.4 per cent (SE 1.2). This pattern was consistent across all stratifying variables.

Only 15.9 per cent (SE 1.1) of all respondent companies indicated an identifiable budget allocation for health promotion activities; 55.3 per cent (SE 3.5) did not know the amount allocated for the current year. Distribution of known budget allocations were $1–999 at 7.6 per cent (SE 1.9); $1,000–9,999 at 14.2 per cent (SE 2.5); $10,000–99,000 at 17.3 per cent (SE 2.7); and $100,000–500,000 at 4.8 per cent (SE 2.0).

Discussion

Compared to results of statewide surveys performed during the five years prior to this survey, this national survey suggests large prevalence increases in overall health promotion activity, smoking cessation, nutrition education, and stress management; smaller increases were found in exercise/fitness; and no increase noted in weight control. Although methodological differences between surveys and lack of information on the life cycle of health promotion activities make any statements of trends tentative, the fact that greater than 50 per cent of the activities were in place for fewer than five years lends support to growing prevalence of these activities.

Employees at the 750+ worksites are at least twice as likely to have each type of activity as employees in <100 worksites, with prevalence ratios of about 5:1 for blood pressure control and treatment, weight control and nutrition education; 4:1 for stress management; and 3:1 for health risk assessment, exercise/fitness and off-the-job accident prevention. The increased likelihood of large worksites having one or more activities may be due to increased likelihood of dedicated personnel, benefits and health staff. Although regional differences are generally small, the south has a much lower prevalence for smoking cessation, which may relate to higher tolerance for smoking, concern for potential adverse regional economic effects of reduced tobacco consumption, and less state and local governmental action to restrict smoking. The south and northeast share a low relative prevalence of both health risk assessment and stress management. These differences do not correspond to known risk factor differences among employees at different size worksites.

No consistent rank order of prevalence exists among industry types although worksite size may be a confounding variable. A disproportionate number of UTC and FRI worksites are in the two largest categories, while the reverse is true for "wholesale/retail" and "other." Higher industry prevalence of some activities may reflect the type of work performed. MAN, OTH and UTC, associated with strenuous physical activity, have high rank order prevalence of back problem prevention and care activities. The need for many SER personnel to interact with customers may explain the high prevalence of smoking cessation activities, particularly smoking policies.

Prevalence rates for each of the two types of employee participation activities with the greatest evidence for effectiveness—smoking cessation and blood pressure control—are below 20 per cent, suggesting considerable expansion opportunities. Health risk assessment identifies reducible risks, and its results are frequently used to direct participants to specific behavioral change programs. Health risk assessment also supports program evaluation. Greater use of this instrument could therefore increase participation in other types of health promotion activities and permit better tracking of individual and group progress.

Although the contribution of worksite health promotion activities to achieving national health promotion objectives cannot be gauged from this study, all nine activity types support specific awareness and risk reduction objectives and their availability to tens of millions employees suggests that

the workplace be considered an important delivery site in any national risk education effort.

ACKNOWLEDGMENT

This study supported by DHSS/PHS/Office of Health Promotion and Disease Prevention and the Office of the Assistant Secretary for Planning and Evaluation under Contract Number 282-84-0089, with additional funding provided by Johnson & Johnson Health Management, Inc. The findings were presented at the meeting of the Society for Prospective Medicine, October 1987. The authors wish to thank Martha Carmel for her valuable contribution to this project.

The Paul B. Cornely Postdoctoral Program for Minority Scholars at U-MI SPH

The University of Michigan School of Public Health has completed its first round of admissions to the post-doctoral fellowship program for minority scholars, initiated last year. The first three postdoctoral fellows began their studies last September in this two-year program:

- Thomas LaVeist received his PhD in Sociology from U-MI in 1988, and his dissertation focused on Black-White differences in infant mortality.
- Dawn Smith, MD, recently completed her MPH in Public Health Policy and Administration from U-MI and is currently working on an AIDS intervention project.
- Dr. Verna Keith was an Assistant Professor of Sociology at the University of Texas, doing work on Black-White differences in physician utilization using the National Center for Health Statistics Health Interview Survey.

The program at U-MI School of Public Health has been named the Paul B. Cornely Postdoctoral Program for Minority Scholars. Dr. Cornely is an alumnus of the University of Michigan, having received his bachelor's degree there in 1928, his MD degree in 1931, and his DrPH in 1934. Dr. Cornely was the first Black American to earn a doctorate in a public health specialty. A long-time resident of Washington, DC, he was Director of the Howard University Hospital from 1947 to 1958; founder and first President of the District of Columbia Public Health Association; and the first Black President of the American Public Health Association.

Dr. Cornely has served on a number of White House Presidential Commissions and is an honorary fellow of the Royal Society of Health and of the American College of Hospital Administrators.

For further information about the post-doctoral fellowship, contact: Jan O'Connor, Woody Neighbors, or Marshall Becker, Dean's Office, University of Michigan School of Public Health, Ann Arbor, MI 48109.

National Trends in the Use of Preventive Health Care by Women

Diane M. Makuc, DrPH, Virginia M. Freid, BSN, MS, and Joel C. Kleinman, PhD

Abstract: This study investigates national changes between 1973–74 and 1985 in women's use of three preventive health services based on data from the National Health Interview Survey. Smoothed proportions of women with recent preventive care were estimated using weighted least squares for subgroups categorized by age (20–39, 40–59, 60–79), race (White, Black), income (poor, nonpoor), and year of interview. Older women and Black women experienced the largest increases in recent use of clinical breast examinations and Pap tests. Between 1973 and 1985 changes in recent breast examination ranged from zero for White women ages 20–39 years to a 23 percentage point increase (95% CI = 17,30) for Black women ages 60–79 years. A similar pattern was found for Pap testing. Changes between 1974 and 1985 in recent blood pressure testing ranged from zero for women ages 20–39 years to an 8 percentage point increase (95% CI = 6,10) for women ages 60–79 years. Despite the increases among older women, in 1985 recent use of breast exams and Pap tests remained lower among older women. Further, the poor remained less likely than the nonpoor to have recent preventive care (except blood pressure testing among older women). Most women without recent cancer screening tests had a recent physician contact, highlighting the need for greater emphasis on cancer prevention by health care providers. (*Am J Public Health* 1989; 79:21–26.)

Introduction

Since the late 1970s, there has been increasing interest in organizing health promotion and disease prevention activities for the American people. In a 1979 report, the US Surgeon General stressed that future reductions in morbidity and mortality were linked to the widespread adoption of preventive practices.[1] In 1979, the Canadian government also issued a landmark report highlighting prevention activities by recommending the replacement of the routine annual physical examination with a lifetime program of health promotion activities.[2] Canadian and US task forces are continuing to evaluate the scientific merit of specific preventive health measures to develop age- and sex-specific health screening recommendations.[3]

This article presents national changes between 1973–74 and 1985 in the use of three major preventive health services available to women: clinical breast examination, Pap smear testing, and blood pressure measurement. These widely accepted and commonly available preventive techniques have the potential to significantly decrease the levels of disease and disability among women. In this paper we investigate how changes over time in the use of these three preventive services vary by age, race, and income, and whether the subgroups at greatest risk of disease are as likely to receive preventive care as those at lower risk of disease.

Breast Cancer

Breast cancer, a leading cause of cancer deaths among women, accounted for 40,093 deaths in the United States in 1985.[4] Between 1973 and 1985, the age-adjusted breast cancer incidence rate has increased an average of 1 per cent each year, while the age-adjusted death rate for breast cancer has remained about the same.[5] The incidence of breast cancer among White women was almost 20 per cent greater than for Black women in 1985. However, Black women are at significant disadvantage to White women in terms of prognosis; only 62 per cent of Black women survive five years compared to 75 per cent of White women. Part of this difference is because Black women are less likely than White women to have localized disease at time of diagnosis (41 versus 49 per cent), but controlling for the stage of disease does not eliminate the disadvantage to Black women.[5]

Public health efforts have aimed to increase the detection of localized breast cancer through a three-pronged approach of breast self-examination, periodic clinical examination by a health care provider, and mammography.[6] The effectiveness of mammography and clinical breast exams in reducing mortality has been demonstrated among middle-aged and older women. However, the effectiveness of breast self-examination is less clear.[6] The American Cancer Society recommends a breast exam by a physician every three years between 20 and 40 years of age and an annual exam after age 40.[7] The American College of Obstetricians and Gynecologists (ACOG) recommends "regular periodic" breast exams.[8]

Cervical Cancer

In 1985, cervical cancer caused the deaths of 4,508 women in the United States.* Between 1973 and 1985 the age-adjusted incidence rate of invasive cervical cancer decreased 35 per cent, and the death rate for cervical cancer declined by 38 per cent.[5] Death rates have been declining at about the same rate, regardless of age or race.* In 1985 the age-adjusted incidence rate was twice as great for Black women as for White women and the age-adjusted death rate was two and half times as great.[5] Death rates and incidence rates for invasive cervical cancer also increase with age.

The appropriate frequency and ages for Pap test screening remain controversial.[9] Prior to 1980 the American Cancer Society actively advocated annual Pap tests for all women; in 1980 the Society changed its recommendation to an annual Pap test for two negative examinations and then at least every three years until the age of 65. A similar recommendation was made at a 1980 Consensus Development Conference at the National Institutes of Health. In contrast, the American College of Obstetricians and Gynecologists (ACOG) continues to recommend annual screening for "most women in the United States." The American Cancer Society is once again emphasizing annual Pap smears. The test frequency can be decreased at the discretion of the physician after three consecutive annual negative tests.[10] A national survey of

recently trained obstetricians and gynecologists found that over 97 per cent usually recommend annual Pap testing for women aged 20 to 59 years, and the majority of physicians (66–72 per cent) strongly disagree with the statement that "routine" Pap tests are not needed for women over the age of 65.[9]

Hypertension

About 22 million adult women ages 18–74 years (30 per cent) had elevated blood pressure readings (systolic blood pressure of at least 140 mmHg or diastolic blood pressure of at least 90 mmHg) during 1976–80.[11] The proportion of women with elevated blood pressure rises steadily with age, from 7 per cent of women 18–24 years to 64 per cent of women 65–74 years. Black women of all ages are at substantially higher risk of elevated blood pressure than their White counterparts.[11]

Mortality from heart disease and stroke has declined steadily since 1950 among women, partially due to decreases in undiagnosed and/or untreated hypertension.[11] Despite the gains of the past few decades, the detection of hypertension remains an important issue. The Joint National Committee on Detection, Evaluation and Treatment of High Blood Pressure has recommended that a blood pressure screening be conducted at every visit with a health professional or at least once every two years.[12]

Methods

This study uses data from the National Health Interview Survey (NHIS), a continuing household survey conducted by the National Center for Health Statistics (NCHS). The NHIS is a national probability sample of the civilian noninstitutionalized population of the United States. Each year the sample includes about 40,000 households. Information regarding health and other characteristics of household members is obtained through interviews in the household. Questions regarding the use of Pap tests and clinical breast examinations were included in the 1973 and 1985 surveys.[13,14] The use of blood pressure tests (taken by a physician or other health professional) was included in the 1974 and 1985 surveys.[14,15] In 1973 the entire NHIS sample received questions on use of preventive services (about 40,000 women). In 1974 and 1985, one-third of the NHIS sample received questions on preventive health care (about 15,000 women). In the 1973, 1974, and 1985 surveys interviews were completed for 96–97 per cent of all eligible households. Response rates to the three prevention questions vary from 96 to 98 per cent among those who received these questions.

Changes in use of preventive care are investigated for women in 12 subgroups based on age (20–39, 40–59, 60–79), race (White, Black), and income (poor, nonpoor). A poverty variable was constructed based on family income and family size using the 1973, 1974, and 1985 poverty threshold definitions.[16–18] Poor women were defined in this analysis as those with family income below 125 per cent of the poverty level for their family size. Information on family income was available for 93 per cent of the women in 1973 and 1974, and 89 per cent in 1985. Women with missing income data are excluded from estimates by income, but included in estimates which do not require data on income.

For each of the preventive services, trends in the per cent with a recent test are analyzed. Recent testing is defined as less than two years prior to the interview for Pap tests and breast exams and less than one year for blood pressure tests. In addition, changes in the per cent who have never had each test are examined. Smoothed proportions with a recent test were calculated for 24 subgroups of women based on age, race, income, and year of survey using linear models and weighted least squares.[19] The computer programs SURREGR[20] and SESUDAAN[21] were used to calculate observed proportions, variances, and covariances. These programs use Taylor series linearization to calculate variances that take into account the complex survey design of the NHIS. The 1985 NHIS sample weights were truncated at their 90th percentile because of the large variability in the sample weights for the 1985 NHIS health promotion and disease prevention supplement. The computer program GENCAT[22] was used to calculate smoothed proportions of women with a recent test by fitting linear models to the observed proportions. Because of the large differences in utilization according to age, model parameters were estimated separately by age using models nested within each age group. Saturated models (containing all possible interactions) were reduced by eliminating model parameters with a p value less than 0.10 in a hierarchical manner. Two additional interaction terms (with p values of 0.092 and 0.074, respectively) were eliminated because they had little effect on the smoothed per cents or the goodness of fit of the models. Results of goodness of fit tests and hypothesis tests for parameters in the final reduced models are found in the Appendix Table.

An additional analysis of the 1985 data partitions the per cent of women without a recent Pap test and breast exam into two groups, those who had a physician contact less than two years ago and those who did not. Contact with a physician includes contact with associated staff such as nurse practitioners and physician assistants. Apparent inconsistencies in response to questions regarding the time intervals since last physician contact and last Pap test and breast exam occurred for 1–1.5 per cent of women (e.g., a screening test was less than two years ago, but last contact with a physician or assistant was two or more years ago). The results presented in all tables and figures include these apparent inconsistencies. Analyses were repeated excluding inconsistent responses with virtually no difference in the results.

Results

Breast Exams

Between 1973 and 1985 the age-adjusted per cent with a recent breast exam increased from 66 to 70 per cent overall (Table 1). However, changes over time varied substantially by age and race with older women and Black women experiencing the greatest gains. To examine these trends in greater detail smoothed proportions of women with a recent breast exam were calculated according to age, race, income, and year (Figure 1). Among women 20–39 years of age, the per cent with a recent breast exam did not change for Whites, while it increased by 7 percentage points for Blacks (95% confidence interval = 4,11). Among middle-aged women (40–59 years) the per cent with a recent breast exam increased for women of both races, but to a greater extent for Black women than for White women. In addition, middle-aged poor women of both races showed somewhat greater gains than the nonpoor, so that increases ranged from only 2 percentage points among nonpoor Whites (95% CI = 0,4) to 15 percentage points among poor Blacks (95% CI = 8,22). The per cent with a recent breast exam increased substantially for all women 60–79 years of age, but the increases were greater for Black women (23 percentage points with 95% CI = 17,30)

TABLE 1—Per Cent of Women with Selected Preventive Services within the Past Two Years and Standard Errors according to Age and Race, 1973 and 1985

Age and Race	Breast Exam within the Past Two Years		Pap Test within the Past Two Years	
	1973	1985	1973	1985

20–39 years	77.5 (0.4)	77.9 (0.5)	78.5 (0.4)	77.7 (0.5)
Black	77.0 (1.1)	83.9 (1.3)	78.0 (1.2)	84.6 (1.2)
White	77.6 (0.4)	77.0 (0.6)	78.6 (0.4)	76.7 (0.5)
40–59 years	62.1 (0.5)	66.0 (0.9)	59.5 (0.5)	59.9 (0.9)
Black	54.8 (1.4)	67.9 (2.2)	53.2 (1.6)	63.1 (2.4)
White	62.9 (0.5)	65.7 (0.9)	60.2 (0.5)	59.5 (0.9)
60–79 years	44.3 (0.6)	56.2 (0.9)	37.6 (0.6)	43.1 (0.9)
Black	39.1 (2.1)	64.5 (2.3)	31.2 (2.3)	50.4 (2.6)
White	44.7 (0.6)	55.4 (0.9)	38.2 (0.6)	42.4 (1.0)

[a]Age-adjusted by the direct method to the 1985 United States female civilian non-institutionalized population in 10-year age groups.

than for White women (10 percentage points with 95% CI = 8,12) (Figure 1).

In 1985, the per cent with a recent breast exam was 10–13 percentage points lower among the poor than the nonpoor for all age-race subgroups except one (among Black women 60–79 years this difference was only 5 percentage points with 95% CI = −2,13) (Figure 1). Despite the large increases in the use of breast exams among older women, they remain substantially less likely than middle-aged or younger women to have a recent exam in 1985 (56 versus 66 versus 78 per cent) (Table 1). Thus, in terms of age, frequency of breast examination is inversely related to risk of breast cancer. Black women were more likely than White women to have a recent breast exam in 1985 (75 versus 69 per cent), due to the greater increases in use of breast exams among Black women (Table 1).

All subgroups of women experienced large declines in the per cent who never had a breast exam (data available upon request to authors). Between 1973 and 1985, the age-adjusted per cent with no breast exam declined from 16 to 5 per cent. In 1985, the per cent who had never had a breast exam was higher among older women (11 per cent) than middle-aged or younger women (4 per cent). Older poor women were the most likely to have never had a breast exam (18 per cent).

Pap Tests

Trends in the use of Pap tests are similar to those for breast exams, particularly for younger women. This is not surprising because both procedures often occur at the same visit. In 1973 and 1985 the age-adjusted proportion with a recent Pap test was about the same (64 and 65 per cent, respectively) (Table 1). However, certain subgroups of women experienced substantial gains in the use of Pap tests over this period, particularly older women (60–79 years of age) and Black women.

Smoothed proportions of women with a recent Pap test according to age, race, income, and year (Figure 2) reveal trends similar to those for breast examinations. The slight decline in recent testing among young White women may reflect the 1980 changes in the American Cancer Society recommendations regarding the appropriate frequency of Pap tests.

As a result of the changes in Pap test use, in 1985 Black women were more likely than White women to have had a recent Pap test (71 versus 64 per cent), but within each race and age group the poor were still less likely than the nonpoor to have been tested recently (Table 1, Figure 2). In 1985, the per cent with a recent Pap test was 10–13 percentage points lower among the poor than the nonpoor for all age-sex subgroups except one (among Black women 60–79 years of age this difference was 4 percentage points, 95% CI = −3,11) (Figure 2). In addition, although the age differential was somewhat smaller in 1985 due to increases in Pap testing among older women, the per cent with a recent test remained substantially greater for younger women than for middle-aged or older women (78 versus 60 versus 43 per cent) (Table 1). Within each age group substantial variability in test use also remains. Poor White women were the least likely to have a recent Pap test and nonpoor Black women were the most likely (e.g., 47 per cent with 95% CI = 45,50 versus 66 per cent with 95% CI = 61,71 among middle-aged women) (Figure 2).

Although increases in recent Pap test use were limited to Black women and older White women, all subgroups of women have experienced large declines in the per cent who have never been tested (data available upon request to authors). Between 1973 and 1985, the age-adjusted per cent of women who have never been tested declined from 17 to 5

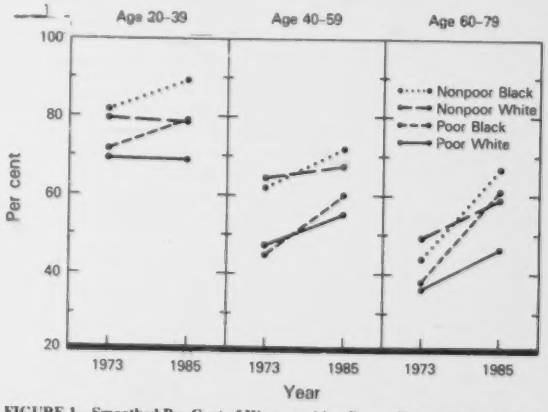

FIGURE 1—Smoothed Per Cent of Women with a Breast Exam within the Past Two Years, according to Age, Race, and Income, 1973 and 1985

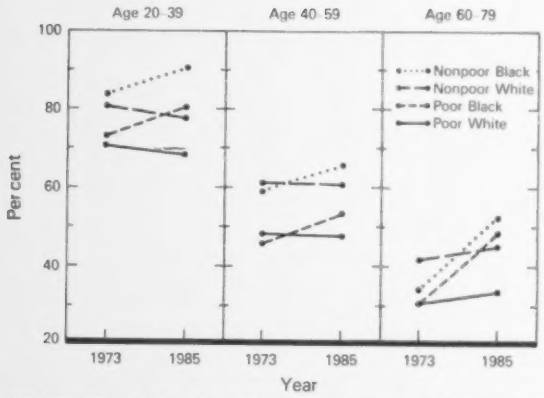

FIGURE 2—Smoothed Per Cent of Women with a Pap Test within the Past Two Years, according to Age, Race, and Income, 1973 and 1985

per cent. In 1985, the per cent who had never had a Pap test was highest among older poor women (18 per cent), the same as for breast exams.

Women without Recent Preventive Care

In Table 2, the per cent of women without a recent preventive screening test has been partitioned according to the time interval since the last physician contact. In 1985, the 30 per cent of women who did not have a recent breast exam included 22 per cent with a physician contact and only 9 per cent without a physician contact. Thus, among women without a breast exam during the past two years, 72 per cent (21.7/30.3) had a physician contact less than two years ago. The proportion of women without a recent breast exam who had a physician contact varied from 66 per cent for middle-aged women to 77 per cent for older women.

The results for Pap testing are similar to those for breast exams. The 35 per cent of women without a recent Pap test included 26 per cent with a physician contact and 9 per cent without a physician contact. Thus, among women without a recent Pap test, 75 per cent had a recent physician contact; this proportion ranged from 71 per cent among middle-aged women to 82 per cent among older women.

The results in Table 2 can also be used to partition the poverty differential in use of preventive care between women who have had a physician contact and those who have not. This provides some insight into whether the less frequent use of preventive care by the poor is primarily a problem of access to health care in general or a lack of emphasis on preventive care among women who have had some contact with the medical care system. For young women (20–39 years) and older women (60–79 years) most of the poverty differential in screening levels occurs among those who have had a recent physician contact. For example, among young women the 7 percentage point difference in use of breast exams between the poor and the nonpoor reflects a difference of 6 percentage points for women with a recent physician contact and only a 1 percentage point difference for women without a recent physician contact. Among middle-aged women the results are somewhat different. About half of the poverty differential in use of both Pap and breast exams occurs among women with a recent physician contact and the other half of the poverty differential is accounted for by the poverty differential among women without a recent physician contact.

Blood Pressure Measurement

Between 1974 and 1985, the age-adjusted proportion of women 20–79 years of age with a blood pressure measurement in the past year increased slightly from 76 to 79 per cent (Table 3). Examination of the smoothed proportions for the three age groups shows that the changes over time were the same for White and Black women and poor and nonpoor women. However, changes in the proportion with a recent blood pressure test increase with successive age groups. Older women (60–79 years) experienced the largest increase of 8 percentage points (95% CI = 6,10) (Figure 3). Unlike the results for Pap and breast examinations virtually all women had experienced a blood pressure test in their lifetime in 1974 and 1985.

In 1985, differences by race and income in the use of blood pressure testing were apparent for women under the age of 60. Consistent with their greater risk of hypertension, Black women were more likely than White women to have had a recent measurement. Among women under age 60, poor White women were least likely to be tested (72–73 per cent) and nonpoor Black women were most likely to be tested (83–86 per cent) (Figure 3). Among women 60–79 years of

age, 84 per cent reported a recent blood pressure test in 1985, regardless of race or income (Figure 3). In contrast to the findings for Pap and breast examinations, the proportion with a recent blood pressure test did not decrease with advancing age. In 1985, young (20–39 years) and middle-aged women (40–59 years) were equally likely to be tested, and older women were the most likely to have had their blood pressure tested recently.

Discussion

Between 1973–74 and 1985, some encouraging changes occurred in the use of preventive health screening. The proportion never screened for breast or cervical cancer declined sharply for all subgroups of women. Recent screening tests for cervical cancer, breast cancer, and hypertension increased among older women who are at increased risk of these diseases. In addition, recent screening tests for cervical and breast cancer increased for Black women who are at higher risk for cervical cancer and are more likely to have advanced stages of breast cancer at the time of diagnosis.

Increases in preventive care for Black women occurred in all age groups and for both poor and nonpoor Black women. The consistency of the increases in preventive care across all subgroups of Black women, in contrast to the much

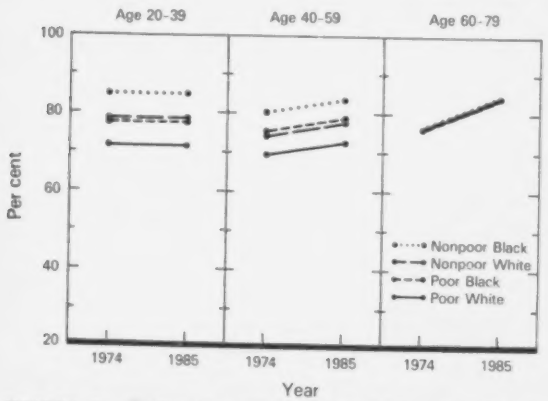

FIGURE 3—Smoothed Per Cent of Women with a Blood Pressure Test within the Past Year, according to Age, Race, and Income, 1974 and 1985

smaller changes (or no change) observed for the corresponding subgroups of White women, is noteworthy. The greater use of preventive screening tests among Black women in 1985 contrasts sharply with racial differences in the use of early prenatal care. Black mothers are less likely than White mothers to begin care during the first trimester of pregnancy, regardless of age or educational attainment.[23] Racial differences for other measures of ambulatory care use were minimal in 1985.**

Increasing emphasis on the importance of health promotion and preventive practices between 1973 and 1985 may have contributed to the increases in use of preventive care. Several large screening programs were established including the breast cancer detection demonstration project,[24] the community hypertension evaluation clinic program,[25] and the national high blood pressure education program.[26] Such programs can heighten awareness of the need for prevention among both health care providers and consumers. Also during this period, women's magazines and the popular press have publicized the importance of preventive health screenings.

Despite the gains since 1973 among Black and older women, inequities remain in the use of preventive care. In 1985, poor women of all ages and races were less likely than their nonpoor counterparts to have recent preventive screenings (except blood pressure measurement among older women). Older women remain less likely to have had a recent breast exam or Pap test, despite the fact that the incidence of these diseases rises sharply with age. In addition, poor women and older women were more likely to never have received breast or Pap screening in their lifetime. Lower levels of recent Pap testing with increasing age may be partially related to the high prevalence of hysterectomies. Data from the 1982–84 NHANES I Epidemiologic Follow-up Study show that 30 per cent of women over the age of 40 reported having had a hysterectomy.*** However, the American College of Obstetricians and Gynecologists recommends continued cytologic testing even for women who have had hysterectomies.

Most women who did not have a recent Pap test or breast exam did have a recent contact with a physician. Further, the lower use of screening tests among poor women than nonpoor women is accounted for in large part by women with a recent physician contact. However, among middle-aged women a substantial part of the poverty differential in screening is also accounted for by women without a recent physician contact. The relatively high proportion of middle-aged poor women without a recent physician contact (17 per cent) may reflect a lack of health programs available to poor women in this age group.

Women with recent physician contacts may not receive preventive care for a variety of reasons. Not every contact with a physician presents the opportunity for cancer screening tests. Some physician contacts may be visits to specialists, e.g., ophthalmologists, who do not provide this type of service. Other physician contacts which may be unlikely to include preventive screening tests include visits for acute illnesses, particularly emergency room visits.

**Unpublished data from the National Health Interview Survey, National Center for Health Statistics, and the National Ambulatory Medical Care Survey, NCHS.

***Unpublished data from the National Health and Nutrition Examination Survey (NHANES I) Epidemiologic Follow-up Study, National Center for Health Statistics.

Further efforts to encourage use of preventive care are warranted, especially for selected subgroups of women. In particular, in 1985, the majority of older White women, half of older Black women, and half of middle-aged poor women did not have a recent Pap test. Perhaps even more importantly, among poor White women, the majority of those 60–79 years of age and almost half of those 40–59 years of age did not have a recent breast exam. These low levels of screening for breast and cervical cancer contrast sharply with the much higher levels of blood pressure testing among these subgroups of women, and are due in large part to a lack of emphasis on cancer prevention for women who have had contact with the health care system.

Resistance to Sexual Assault: Who Resists and What Happens?

JUDITH M. SIEGEL, PHD, MSHYG, SUSAN B. SORENSON, PHD, JACQUELINE M. GOLDING, PHD, M. AUDREY BURNAM, PHD, AND JUDITH A. STEIN, MSPH

Abstract: To determine who resists sexual assault and what happens, data were examined from a probability sample of 3,132 adult community residents of Los Angeles, California. Seventy-five per cent of the respondents reporting an assault (n = 365) indicated that they had attempted to resist their most recent assault; talking was the most frequently used resistance strategy. The strongest predictor to emerge in the multivariate analyses of resistance was timing of assault: respondents assaulted only in childhood were less likely to resist than either respondents assaulted only in adulthood, or respondents assaulted in both phases. Univariate analyses indicated that resistance reduced the probability of sexual contact, however multivariate analyses suggested that assailant use of force was the most important determinant of assault outcome. (*Am J Public Health* 1989; 79:27–31.)

Introduction

Legal thought has been concerned with the topic of resistance to sexual assault because victim resistance has been considered the proof that sexual overtures are unwanted. Victims of sexual assault are unique in this respect—victims of no other violent crime are expected to meet their assailant with resistance.[1] While most states no longer require proof of resistance in criminal rape proceedings, societal norms still emphasize resistance as one way to legitimize a victim's claim that sexual contact was unwanted.

Research on resistance to sexual assault has focused largely on the relative effectiveness of various strategies in deterring assault and physical injury. Conclusive statements about strategy effectiveness have been preempted, however, by the variability in definitions of resistance across studies. For example, screaming has been alternatively grouped with other verbal strategies or with more aggressive physical strategies. Studies of resistance have been limited also by their reliance on respondents who report assault to the police or who utilize rape crisis centers. Biased estimates of the probability of resistance may emerge because reported assaults are known to differ in important ways from non-reported assaults,[2] and the dimensions on which these assaults differ may be related in turn to the use of specific resistance strategies. Successful resistance strategies (those deterring assault) may be under reported as well.[3–5] Despite these biases and definitional problems, the empirical research converges to support one important conclusion: resistance reduces the probability of an assault being completed.

Fewer studies have examined the relation between resistance and physical injury other than rape. Two investigations suggest that resistance may be costly to the victim in terms of physical injury.[6,7] In contrast, other researchers[8,9] conclude that resistance does little to increase one's chances of injury. One analysis that took timing into account addresses this apparent contradiction.[10] While a variety of resistance strategies are associated with increased victim injury, the chronology shows that victim resistance increases in response to injury. These and other data[11] led Furby and Fischhoff[3] to suggest that more assertive strategies are associated with greater chances of injury, but these strategies are consequences, not causes, of increased injury.

The research reported here differs from most studies of resistance because the sample is community-based and the respondents are not selected specifically because of their sexual assault experience. Also, data are gathered from men, as well as women, and from Hispanics, as well as Whites who are not Hispanic. (Prevalence of assault for this sample is reported elsewhere.[12,13]) The first aim of this research is to determine the degree to which demographic characteristics and circumstances of assault are associated with resistance strategy. One prior study found that female rape victims reported greater resistance if they knew their assailant, if no weapon was present, and if they displayed certain personality characteristics (such as dominance and internal locus of control).[14]

Like other investigations, this research also examines the relation of resistance to assault outcome, including physical injury. Multivariate analyses allow for a test of independence among the variables associated with resistance or outcome.

Methods

The data are from the Los Angeles Epidemiologic Catchment Area (ECA) study, one of five sites of the National Institute of Mental Health (NIMH)-initiated collaborative ECA program. Respondents at the Los Angeles site were also asked a series of questions regarding lifetime sexual assault. The design and methodology of the ECA surveys are described elsewhere.[15,16]

Sample

The ECA sample consists of 3,132 adults (18 years of age and older) from two catchment areas. One catchment area contains predominantly Hispanic Americans (83 per cent) and the other contains largely non-Hispanic Whites (63 per cent) but also many Hispanics (21 per cent). Eighty-seven per cent of the Hispanic Americans in the two catchment areas are of Mexican origin. Respondents chose whether to take the interview in English or Spanish. The survey instrument allowed easy switching from one language to another.

The sample, stratified by catchment area, was selected using a two-stage probability technique. One adult from each household was randomly selected for inclusion using the Kish procedure.[17] Respondents were interviewed in person, with an overall completion rate of 68 per cent. Among those consenting to the interview, less than 1 per cent (21 of 3,132 respondents) refused to answer the filter question on experience with sexual assault.

The data presented here represent the experiences of the 365 respondents in the Los Angeles ECA sample who provided data about resistance in response to their lifetime experience with pressure or force to have sexual contact. The demographic characteristics of these respondents are presented in Table 1.

Instrument

Lifetime sexual assault was assessed using the question: "In your lifetime, has anyone ever tried to pressure or force you to have sexual contact? By sexual contact I mean their touching your sexual parts, your touching their sexual parts, or sexual intercourse?" Those answering affirmatively were asked if they had ever been forced or pressured for sexual contact before age 16 (childhood sexual assault). Detailed information was collected from all assaulted respondents concerning the most recent assault. Among other questions, respondents were asked: time elapsed since assault; the relation of the assailant to the respondent; the kind of pressure or force used; whether physical harm occurred and when; the type of sexual activity that occurred; and whether resistance strategies were used. (A more detailed description of this instrument is reported elsewhere.[12])

Operationalization of Variables

The data presented here focus on two aspects of resistance to assault: the correlates of resistance and the relation of assault resistance with reported outcome. Respondents reporting any sexual assault were asked the following question: "We are interested in the kinds of situations in which people may decide to resist sexual contact. The most recent time you were pressured or forced into sexual contact did you try to resist?" Respondents who indicated they had tried to resist were then asked: "What did you do?" Interviewers recorded the respondents' answers verbatim.

Correlates of resistance examined in this research include respondent demographic characteristics and assault circumstances:

- The *demographic variables* are: gender, age at interview (dichotomized at younger than 40 years and 40 years or older), ethnicity (Hispanic or other White), and education (dichotomized at the median years of education within ethnic group, i.e., 10 among Hispanics, 14 among other Whites).
- *Circumstances surrounding the assault* are: whether the respondent had experienced one compared to two or more lifetime assaults; whether the most recent assault had occurred during childhood (below age 16) or during adulthood (this group was subdivided into respondents assaulted only in adulthood and those assaulted in adulthood with at least one prior assault in childhood); the time elapsed since this assault; what kind of pressure or force the assailant used (described below); and the respondent's relation with the assailant (described below).

The question on pressure or force asked the respondent to indicate from a list all strategies that applied. For purposes of analyses, these assailant strategies were classified as either *pressure* (they tried to talk you into it; you were afraid they wouldn't like or love you; they bribed you) or *force* (they said they would hurt you; they scared you because they were bigger or stronger; they pushed, hit, or physically restrained you; they threatened you with a weapon; they drugged you or got you drunk; they physically harmed or injured you). Those indicating physical harm were also asked the following three questions: "Were you hurt *before* sexual activity took place?"; "Were you hurt *during* sexual activity?"; "Were you hurt *after* sexual activity had taken place?"

The respondent's relation to the assailant was classified for analyses as stranger, acquaintance (includes friend), intimate (lover, spouse), relative, and other. Regarding assault outcome, respondents were asked: "What kinds of sexual activity resulted?" A list of applicable responses included: none, attempted sexual contact only; they touched your sexual parts (genitals or breasts); they had you touch their sexual parts; intercourse; something else.

TABLE 1—Demographic Characteristics of Respondents Reporting Sexual Assault, Los Angeles Epidemiologic Catchment Area Site

Sex, Age	Mexican American	Other White	Other	Total
Men[a]				
Age (years)				
18–39	28	51	11	90
40+	6	24	3	33
Total	34	75	14	123
Women[b]				
Age (years)				
18–39	46	110	11	167
40+	16	52	2	70
Total	62	162	13	237
Total	96	237	27	360

[a]The data for two men are omitted because they did not report their age.
[b]The data for three women are omitted because they did not report their age.

Results

Resistance Strategies

All responses to the open-ended question on resistance strategies used in the most recent assault were reviewed and content analyzed in order to develop coding categories. Up to two resistance strategies per respondent were coded. Very few respondents reported more than two resistance strategies or refused to answer this question (about 1 percent for each). This content analysis yielded six categories: talking; reasoning; saying no sexual interest; loud or angry talking; fleeing; and physically fighting.

Other resistance strategies were infrequently occurring responses (less than 4 per cent) that could not be classified in these six categories, such as "throwing up" or "making him take me home." Some respondents were classified into the no resistance category, even though they reported they had attempted to resist assault, if their resistance strategy indicated no apparent resistance. Three raters (JMG, JAS, JMS) independently classified each of the open-ended responses. All three raters agreed on the category 90 per cent of the time; two of three raters agreed 98 per cent of the time. The raters discussed the responses for which there was complete disagreement and consensus was achieved.

Table 2 presents the frequencies for reported use of each of the six categories of resistance strategies. These data are presented for all respondents, for men, and for women. As shown in Table 2, talking was the most frequently used resistance strategy (27 per cent), followed by physically fighting (23 per cent). Saying no sexual interest or loud/angry talking were used less often (3 and 4 per cent, respectively), while fleeing (15 per cent) and reasoning (11 per cent) were used more often. Combining all resistance strategies, 75 per cent of the respondents indicated they had attempted to resist their most recent assault.

TABLE 2—Frequency[a] of Use of Resistance Strategies for All Assaulted Respondents, for Women, and for Men

Resistance Strategy	All Respondents n = 365 Per Cent[b]	(n)	Women n = 240 Per Cent[b]	(n)	Men n = 125 Per Cent[b]	(n)
Talking	27	(91)	23	(49)	35	(42)
Reasoning	11	(36)	10	(21)	13	(15)
Saying no sexual interest	3	(11)	3	(6)	4	(5)
Loud/angry talking	4	(15)	7	(15)	0	(0)
Fleeing	15	(49)	17	(36)	11	(13)
Physically fighting	23	(77)	30	(64)	11	(13)
No resistance	25	(84)	22	(47)	31	(38)

[a] Weighted for sample design and non-response.
[b] Percentages do not sum to 100 because respondents could identify multiple strategies.

Correlates of Resistance

To examine the correlates of resistance, the strategies presented in Table 2 were aggregated into verbal resistance (talking, reasoning, saying no sexual interest, loud/angry talking), physical resistance (fleeing, physically fighting), and no resistance. Respondents who indicated use of both verbal and physical resistance were classified with the physical resisters. The findings were unchanged if this latter combination strategy was considered separately.

The rates (per cent reporting) of each resistance strategy were first examined as a function of gender, ethnicity, age, and educational attainment. These rates were calculated using SESUDAAN, a specialized SAS subprogram which calculates rates and asymptotic approximations of exact standard errors in clustered samples.[18] Analyses of ethnicity and educational attainment included only the Hispanic and other White respondents, as only these groups were sufficiently represented in the sample to permit comparison of rates and computation of median educational level.

Age at interview, ethnicity, and educational attainment were unrelated to the use of resistance strategy. Women were more likely to use physical (or combination) resistance strategies than men (46.6 per cent, 99 per cent confidence intervals [CI] = 36.9, 56.3 versus 22.0 per cent, 99 per cent CI = 11.8, 32.2). In contrast, men were more likely than women to use verbal strategies (46.9 per cent, 99 per cent CI = 35.1, 58.8 versus 31.1 per cent, 99 per cent CI = 22.3, 40.7) or no strategies (31.1 per cent, 95 per cent CI = 22.0, 40.2 versus 21.8 per cent, 95 per cent CI = 17.0, 26.7).

Turning to the circumstances surrounding the most recent sexual assault, the number of lifetime assaults, the time elapsed since the most recent assault, and the respondent's relation to the assailant were all unrelated to resistance strategy. Respondents whose most recent assault was during childhood (at age 15 or younger) were more likely to offer no resistance (46.9 per cent, 99 per cent CI=31.1, 62.8) than either respondents assaulted only in adulthood (21.6 per cent, 99 per cent CI = 14.1, 29.2) or those assaulted in both adulthood and childhood (16.5 per cent, 99 per cent CI = 4.7, 28.4). Additionally, respondents assaulted only in childhood were less likely to use verbal resistance (17.7 per cent, 99 per cent CI = 4.4, 31.0) than the two adult groups (44.4 per cent, 99 per cent CI = 33.9, 54.8 and 32.2 per cent, 99 per cent CI = 19.2, 45.2, respectively). Use of physical or combination of strategies was equivalent for those assaulted only in childhood (35.4 per cent) or only in adulthood (34.0 per cent), and was more prevalent among respondents assaulted during both life phases (51.2 per cent, 99 per cent CI do not overlap with other groups). Respondents whose assailant used pressure were more likely to use verbal strategies (46.0 per cent, 99 per cent CI = 35.8, 56.3) than were respondents whose assailants used force (21.3 per cent, 99 per cent CI = 9.7, 32.9). Complementary findings emerged for physical or combination strategies: these strategies were more common among those experiencing force (56.9 per cent, 99 per cent CI = 40.8, 73.0) than pressure (26.3 per cent, 99 per cent CI = 15.7, 36.8). The probability of offering no resistance was unrelated to the assailant's use of pressure (27.7 per cent) or force (21.8 per cent).

To control for the possibility of shared variance among the correlates of resistance, all variables were examined simultaneously in a logistic regression analysis, using the SAS CATMOD procedure.[19] For this analysis, resistance was categorized as a dichotomous (yes,no) variable. As shown in Table 3, developmental timing of assault was the strongest predictor of resistance. Respondents assaulted only in childhood were less likely to resist than either respondents assaulted only in adulthood (odds ratio [OR] = .18, 95 per cent CI = .60, .52) or respondents assaulted in both life phases. Inclusion of all two-way interaction terms in the model did not increase the ability to predict resistance.

Relation of Resistance to Assault Outcome

Assault outcome was examined in three ways. First, outcome was dichotomized as aggregated categories of: contact (they touched your sexual parts, they had you touch their sexual parts, intercourse, something else involving contact, e.g., oral sex) compared to no contact (category of none, attempted sexual contact only). Second, outcome was dichotomized as intercourse (oral, anal, or vaginal) compared to all other outcomes, and third, outcome was dichotomized into categories of physical harm compared to no harm. Data on physical harm were obtained from the question on the type of pressure or force utilized by the assailant; one response option was, "They physically harmed or injured you."

The rates (per cent reporting) of each resistance strategy were examined as a function of contact, intercourse, and physical harm. Those experiencing contact were more likely to employ no resistance strategy (31.2 per cent, 99 per cent CI = 23.5, 38.9) than those with no contact (13.1 per cent, 99 per cent CI = 5.4, 20.9). The two groups were equally likely to employ physical plus combination strategies (38.8 per cent compared to 37.7 per cent), and those experiencing no contact reported a greater use of verbal strategies than those with contact (48.1 per cent, 95 per cent CI = 36.6, 59.7 versus 31.1 per cent, 95 per cent CI = 25.2, 37.1). Data on intercourse as an outcome compared to the aggregated categories of all other sexual activity showed no relation with resistance.

TABLE 3—Predictors of Resistance to Sexual Assault: Multiple Logistic Regression Analysis

Variables	Coefficient	S.E.	Odds Ratio	95% Confidence Interval Limits	
				Lower	Upper
Sex (Female, Male)	−0.09	0.19	0.92	0.63	1.35
Age at Interview (40 or Above, Below 40)	−0.40	0.21	0.67	0.45	1.01
Ethnicity (Other, White, Hispanic)	0.14	0.19	1.14	0.79	1.64
Education (Above Ethnic-Specific Median, Below)	−0.12	0.18	0.89	0.62	1.27
Number of Lifetime Assaults (2 or more, 1)	−0.28	0.22	0.76	0.50	1.16
Timing of Assault					
Childhood only vs Adulthood only	−1.69	0.54	0.18	0.06	0.52
Childhood only vs. Child and Adulthood	−2.15	0.70	0.12	0.03	0.45
Assault Recency (Above Median, Below)	−0.10	0.21	0.90	0.60	1.35
Assailant Method (Force, Pressure)	0.11	0.18	1.12	0.78	1.61
Relation to Assailant (Known, Stranger)	0.01	0.23	1.01	0.65	1.57

Likelihood ratio = 0.67

To determine whether resistance was related to assault outcome independently of other potential correlates of outcome, resistance, demographic variables, and characteristics of the assault were all included as predictors of assault outcome (contact, intercourse) in logistic regression analyses. The most important determinant of contact was assailant use of force, with force (OR = 1.62, 95 per cent CI = 1.21, 2.17) more likely to result in contact than pressure. The probability level for the likelihood ratio chi-square for this regression model was very low (.01), suggesting that the model was not a good fit. Inclusion of all two-way interaction terms did not improve model fit. Thus, these results should be viewed as tentative.

Predicting intercourse with these variables resulted in the same effect for assailant use of force. Specifically, force was (OR = 1.41, 95 per cent CI = 1.06, 1.87) more likely to result in intercourse than pressure. The other independent predictor was time of assault: those assaulted only in adulthood (OR = 1.83, 95 per cent CI = 0.05, 0.50) and those assaulted both in adulthood and childhood were (OR = 1.70, 95 per cent CI = 0.05, 0.62) more likely to have intercourse than those assaulted only in childhood. Similar to the regression predicting contact, the probability level of the likelihood ratio chi-square was quite low.

Turning to the data on physical harm, respondents who reported that they were physically harmed were more likely to report the use of physical plus combination resistance strategies than respondents reporting no harm (67.6 per cent, 99 per cent CI = 43.5, 91.8 compared to 35.3 per cent, 99 per cent CI = 26.9, 43.6), and they were less likely to report verbal resistance than respondents who were not harmed (16.1 per cent, 99 per cent CI = 0.2, 32.2 compared to 39.2 per cent, 99 per cent CI = 31.0, 47.3). A similar trend emerged for no resistance strategy (16.2 per cent, 95 per cent CI = 2.7, 29.8 compared to 25.6 per cent, 95 per cent CI = 20.2, 30.9). To further explore the relation between physical harm and sexual assault, data concerning when the physical harm occurred were examined. Of the 34 respondents who reported physical harm, 29 answered the questions about when harm occurred. For 23 respondents (79 per cent), harm took place before sexual activity; 6 respondents (21 per cent) reported being hurt during or after sexual activity exclusively. Data were not gathered on when resistance was offered.

Discussion

These data, gathered from a probability sample of community respondents, are the first to address comprehensively, and with multivariate analyses, the question of who resists sexual assault. In both univariate and multivariate analysis, individuals whose most recent assault occurred in adulthood (age 16 or older) are more likely to report they resisted than individuals whose most recent assault occurred in childhood. Several factors may contribute to the lower likelihood of resistance among children and adolescents. Children may be more trusting of others and less able to distinguish at onset an act of affection from an attempt at sexual contact. This is exacerbated by less restrictive societal norms for touching a child (in a non-sexual way) compared to touching an adult. Further, children are socialized to be deferent and obedient, particularly to those in positions of authority or power. Respondents assaulted only in adulthood were equally likely to resist as those assaulted in adulthood and childhood, but the strategies of the two groups differed. Respondents assaulted during both life phases reported greater use of physical strategies and less use of verbal strategies.

Univariate analyses show that resistance strategy matches assailant strategy, i.e., use of force by the assailant is associated with physical resistance by the victim, and use of pressure by the assailant is associated with victim verbal resistance. The finding that women are more likely than men to utilize physical resistance probably reflects that for those describing an adult assault, harm or threat of harm is more frequently reported by female than male respondents.[13]

Regarding the relation between resistance and outcome of assault, our univariate analyses corroborate prior research in

showing that resistance, particularly verbal, reduces the probability of sexual contact. Physical resistance, on the other hand, is associated with increased likelihood of contact. These effects did not emerge in multivariate analyses, suggesting that the relation of resistance to outcome is a function of other variables measured in this study, most likely assailant use of force. Also relevant to assault outcome is that physical harm relative to no harm was associated with greater use of physical resistance strategies. The majority (79 per cent) of those harmed indicate that harm commenced prior to sexual activity; thus like other investigations,[10,11] these findings imply that physical resistance is more likely to be a consequence of the sexual assault rather than provoking further injury. Taken together, these results suggest that assailant use of force is more effective than verbal pressure in accomplishing the assailant's aim, *and* that use of force acts as a stimulus for victim physical resistance.

It is important to note, however, that these data do not describe the resistance experiences of persons who were physically harmed to the point of incapacitation or death.

ACKNOWLEDGMENTS

This research was supported by the Epidemiologic Catchment Area (ECA) Program, a series of five epidemiologic research studies performed by independent research teams in collaboration with staff of the Division of Biometry and Epidemiology (DBE) of the National Institute of Mental Health (NIMH). The NIMH Principal Collaborators are Darrel A. Regier, Ben Z. Locke, and Jack D. Burke, Jr; the NIMH Project Officer is William J. Huber. The Principal Investigators and Co-Investigators from the five sites are: Yale University, U01 MH 34224—Jerome K. Myers, Myrna M. Weissman, and Gary L. Tischler; Johns Hopkins University, U01 MH 33870—Morton Kramer and Sam Shapiro; Washington University, St. Louis, U01 MH 33883—Lee N. Robins and John E. Helzer; Duke University, U01 MH 35386—Dan Blazer and Linda George; University of California, Los Angeles, U01 MH 35865—Marvin Karno, Richard L. Hough, Javier I. Escobar, M. Audrey Burnam, and Dianne M. Timbers.

Two co-authors, Drs. Susan B. Sorenson and Jacqueline M. Golding, were supported by NIMH Research Training Grant MH 14664 during this work.

The authors gratefully acknowledge the contributions of Vivian Brown, Cynthia Telles, and Dianne Timbers to the development of the sexual assault instrument.

"Children at Risk" Conference Set for April in Switzerland

CHILDREN AT RISK: AN INTERDISCIPLINARY HEALTH CONFERENCE—April 8–16, 1989, Hotel de la Paix, Lausanne, Switzerland. Co-sponsored by: Department of Social Work Services, Long Island Jewish Medical Center, New Hyde Park, NY.

CALL FOR PAPERS—A limited number of free papers will be accepted. The topics to be addressed at this international conference are the psychosocial aspects of oncology, nutrition, child life, neonatology, substance abuse, child psychiatry, child abuse and neglect, adolescent medicine, professional education and collaborative practice. Credits: 20 hours Category 1 ACCME, AMA and applied to NASW.

For information: Ann J. Boehme, CMP, Associate Director for Continuing Education, Long Island Jewish Medical Center, New Hyde Park, NY 11042; Telephone: (718) 470-8650.

Breastfeeding Trends in the Philippines, 1973 and 1983

BARRY M. POPKIN, PHD, JOHN S. AKIN, PHD, WILHELM FLIEGER, PHD, AND EMELITA L. WONG, MS

Abstract: This paper examines comparable national surveys of breastfeeding from the Philippines carried out in 1973 and 1983. The probability of breastfeeding at selected infant ages is estimated, using the weighted life table. The conclusions are that a 5 per cent decline in the proportion of infants ever breast-fed occurred during the referenced period, and that median length of breastfeeding remained essentially the same. (*Am J Public Health* 1989; 79:32–35.)

Introduction

In recent years, reports of widespread declines in breastfeeding in developing countries have generated much interest, especially among policy decision makers.[1–3] A number of studies have documented changes in the extent and duration of breastfeeding in developing countries (Table 1). Results are mixed, with some countries showing definite declines in either the extent or duration of breastfeeding, while others show increases in the same measures.

Breastfeeding declines do not necessarily follow rapid economic growth, as the examples of Taiwan,[4] Malaysia,[5,6] or South Korea[7] seem to suggest. In studies of Thailand,[8] Mexico,[9] and Panama,[10] economic growth during the time periods of analysis was considerable, yet the declines in breastfeeding were not as extensive as those observed in Taiwan or Malaysia (during the 1950–70 period).[4]

Patterns of decline in breastfeeding across population subgroups will not necessarily be uniform. In Taiwan (between 1967–68 and 1979–80), the extent and duration of breastfeeding decreased considerably for most socioeconomic groups,[3] but in the Dominican Republic the proportion of women who ever breast-fed actually increased in the urban areas while declining in the rural areas (from 1976 to 1983).[3]

For the Philippines, which has experienced only moderate socioeconomic change in the last decade, available studies present somewhat conflicting evidence about changes in breastfeeding behavior. While the country has been cited as one of those with large declines in breastfeeding,[11,12] the evidence on which the claim is based is derived from two noncomparable samples of women.[13,14] A recent review of a large number of small unrelated Filipino surveys concludes that there is little evidence either of a strong downward trend (since 1965) in the proportion of Filipino infants ever breast-fed, or of a significant decline (from 1960 to 1977) in the average duration of breastfeeding.* Zablan[15] also found only a minor decline in the extent of breastfeeding, and no change in breastfeeding duration.

TABLE 1—Summary of Selected Studies on Breastfeeding Trends in Developing Countries*

Country	Period of Analysis	Breastfeeding: Extent	Breastfeeding: Duration
Countries Which Experienced Rapid Economic Development			
Taiwan[1,3,4]	1967–68 to 1985	decrease	decrease
Malaysia[5,6]	1950 to 1970	decrease	decrease
	1970–74 to 1975–77	increase	constant
Korea[6]	1950 to 1970	constant	decrease
Singapore[3]	1951 to 1971	decrease	N/A
	1971 to 1980	increase	N/A
Countries with Lower Levels of Socioeconomic Development			
Thailand[9,10]	1969 to 1979	N/A**	decrease
	1975 to 1979	constant	N/A
	1979 to 1984	increase	increase
Mexico[11]	1976 to 1979	decrease	increase
Panama[12]	1976 to 1979	decrease	decrease
Jamaica[3]	1976 to 1983	increase	increase
Sri Lanka[3]	1975 to 1982	increase	constant
Guatemala	1978 to 1983	N/A	constant

Methods

We analyzed data from the 1973 and 1983 National Demographic Surveys (NDS) of the Philippines, both of which had nationally representative samples of ever-married women, drawn by multistage stratified cluster sampling. Subsamples of 3,573 and 5,396 ever-married women and children from the 1973 and 1983 original samples, respectively, were used in the analysis. The results are based on Filipinos living in private households containing at least one ever-married woman at least 15 years old who had borne at least one child in the three years preceding each survey.

The original sampling weights assigned to the members of the subsamples are adjusted to preserve nationally representative patterns. Results on population composition, breastfeeding extent and duration all are based on the weighted subsamples.

The multiple-decrement life table procedure is used to compute the probability that a child is breast-fed at each age in months and thus the median duration of breastfeeding. The selected ages for which subgroup analyses are carried out are four, seven, and 13 months.

For both time periods there is strong heaping in the reports of cessation of breastfeeding at 12 months of infant age. This may reflect an actual tendency to stop at that age or an exaggeration because of digit preference in reporting. A small longitudinal study in the Philippines showed that the

*Simpson-Hebert M: Infant feeding in the Philippines 1955–1983 and its effect on infant health: A literature review (unpublished manuscript). Quezon City, Philippines: Institute of Philippine culture, 1983.

proportion of infants[16] peaked at age 10–12 months. The same phenomenon was observed in a large scale longitudinal infant-feeding study of 3,080 infants conducted in the Cebu region from 1983 to 1985.**

Some of those who actually stopped breastfeeding at 10 to 11 months report a longer duration of one year, while some of those who actually stopped at 13 or 14 months report a shorter duration of one year. If the errors are spread symmetrically around the 12-month point, no bias in the estimated mean should result.

We chose to compare the median instead of mean duration, because the former is not likely to be as badly biased when there is digit heaping in reported duration.

Results

Breastfeeding, Socioeconomic and Demographic Trends

Changes in Population Composition—A number of selected demographic and socioeconomic indicators hypothesized to be associated with breastfeeding initiation,[17,18] suggest that from 1973 to 1983 the Philippine population not only became more urbanized, but also continued to concentrate in disproportionate numbers in the greater Manila area. Educational levels among ever-married females of ages 15 to 49 and their husbands rose substantially. There was a rise in the median level of real household income (at 1983 levels), and a doubling of the proportion of households with electricity. Occupations shifted from traditional agricultural work toward the unskilled sector, rather than toward the modern skilled sector of the work force.

Changes in household composition were the opposite of what one might expect in a modernizing society: the proportion of extended households increased by 4 per cent from 1973 to 1983, probably the result of rural-urban migration combined with the tendency of the immigrants to board with relatives or acquaintances; average household size declined with a slowly falling birth rate in the country (mean parity declined by about half a child, and contraceptive practice became more common).

Trends in the Extent of Breastfeeding

Figure 1 shows the likelihood of a child being breast-fed according to age by urban residency and by the two time periods of interest. The percentage shown as breast-fed at age 0 is the proportion "ever breast-fed." Table 2 presents information on the proportion of mothers who ever breast-fed classified by selected socioeconomic and demographic groups.

The data indicate a 5.4 per cent overall decline, over the 10-year period, in the percentage of infants ever breast-fed. This decline is consistent with that of Zablan[15] who reported about four percentage points decline from 1973 to 1978 and no decline from 1978 to 1983.

The downward trend is more pronounced in urban than rural areas. A larger decline in breastfeeding occurred among persons residing in Manila and Mindanao than among residents of other areas. Declines also occurred among women with 4–9 years of formal education and among women whose husbands had "mixed" or "traditional" occupations. Women in "modern" occupation or with at least 10 years of education increased breastfeeding initiation.

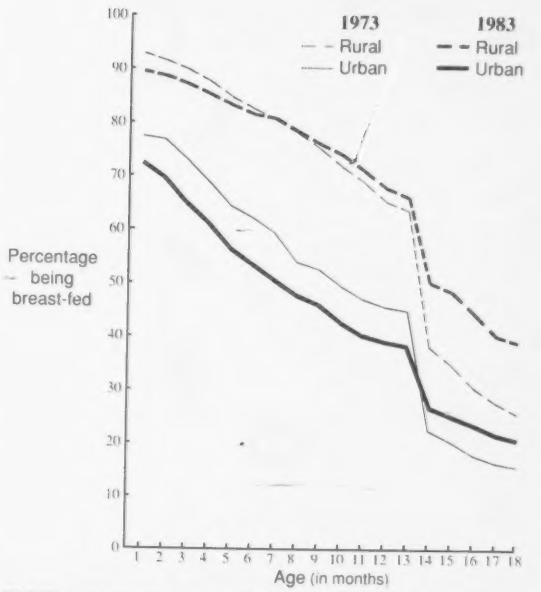

FIGURE 1—Percentage of Urban and Rural Children Breast-fed According to Age in Months, Philippines, 1973 and 1983.

Trends in the Median Duration of Breastfeeding

The median age of the infant at which breastfeeding ceased did not change from 1973 to 1983.*** Decrease in duration occurred among urban and Manila residents, women whose husbands had "modern" occupations, and women who were engaged in market activities. The decrease in these groups was due mainly to breastfeeding cessation in the first year of life. However, relatively large increases in the duration of lactation also occurred between 1973 and 1983 among rural residents, Visayan residents, women with 10 or more years of education, and women with traditional occupations. The increase for these subgroups occurred because in 1983 they were more likely to breastfeed their infants past the first year of life than were similar groups in 1973.

Discussion

We found that from 1973 to 1983 there was a decrease of 5.4 per cent in the extent of breastfeeding and essentially no change in median duration (12.4 in 1973 and 12.5 in 1983). Among women with "modern" occupations, there was an increase in the extent of breastfeeding but no change in median duration. This is not surprising since such women are better educated and better understand the value of breastfeeding, hence more likely to initiate nursing, yet also more likely to provide supplementary food at an early age and reduce duration of breastfeeding because of their occupation.

The decrease in breastfeeding initiation and decreases in probabilities of breastfeeding early in the first year of life are of particular concern because breastfeeding inhibits menstruation

**Cebu Study Team: Unpublished life table results of breast-feeding among Cebu infants, 1983–85. Chapel Hill: Carolina Population Center, University of North Carolina, 1987.

***Zablan (1983) reports an increase of one month of breast-feeding duration from 1978 to 1983; these differences in results may be attributed to the use of different subgroups of children as well as the difference in the technique of estimating duration.

TABLE 2—Incidence of Breastfeeding among Last Live Births Ages 0 to 36 Months at Time of Survey by Selected Characteristics, Philippines, 1973 and 1983 (percentage ever breast-fed, weighted life table results)[a]

Characteristics	Average Sample Size	Incidence		Unadjusted Difference[a]	95% Confidence Interval of Difference

High	892	75.1	69.7	−5.4	−9.9	−0.9

[a]The differences for the total sample between 1973 and 1983 adjusted to keep sample characteristic as equal for the two periods, (i.e., for example to adjust the 1983 urban-rural mix to be the same as that) 1973 are: −4.0, −4.1, −2.1, −2.6, −5.7, −4.6, −3.0 and −4.6 when adjustment is made for area of residence, region, mother's education, father's education, mother's working status, mother's occupation and father's occupation. The 1973 sample composition is used as reference population for the 1983 adjustment.

[b]Information on the location of woman's work is unavailable in 1983.

[c]In 1973, the income levels were based on the father's income while in 1983 the grouping is based on household income.

to some extent, and the protective effects of breastfeeding against morbidity are most pronounced during infancy.[19,20] In a country like the Philippines where health care and contraceptive utilization are limited, decreased breastfeeding initiation may have a deleterious public health impact.

ACKNOWLEDGMENTS

We wish to thank the Government of the Philippines, particularly the National Census and Statistics Office and its Director, Dr. Marcelo M. Orense, and the institutions who along with the Office of Population Studies collected and prepared the NDS data: the University of the Philippines' Population Institute and the Research Institute of Mindanao Culture, Xavier University. We thank Family Health International, in particular Barbara Janowitz, Kathy Kennedy, Shyam Thapa and Nancy E. Williamson for methodological and substantive suggestions and partial funding of this research. We thank the Carolina Population Center for logistical and computer support, and David Guilkey, David Fugate, Mandy Lyerly, Margaret Mauney and Chirayath Suchindran for assistance with this research.

Johnson Foundation Funds Model Program for Elderly in Housing Projects

The Robert Wood Johnson Foundation has awarded grants to 10 state housing finance agencies (HFAs) to develop new ways to finance and deliver support services for frail older people living in federally subsidized private housing for the elderly. Under its Supportive Services Program in Senior Housing, the Princeton-based Foundation has committed up to $4 million over a three-year period to support the efforts of the 10 HFAs. The foundation will provide up to $400,000 to each HFA over the program's duration.

The grants will enable HFAs to work with local housing projects to provide the elderly with needed services such as: arranging emergency medical alert systems, supervising medication schedules, providing transportation, and assisting residents with difficult household chores. The goal of the program is to establish models of service delivery that will enable elderly tenants in subsidized housing to remain independent.

The grant awards will be distributed in two successive phases. An initial one-year grant will fund a planning effort to be reviewed before the two-year implementation grant is approved. During the planning phase, the HFAs will:

- identify housing projects with a significant proportion of people in need of support services;
- assess the training needs of the housing projects' management and staff; and
- develop the financing mechanisms necessary to implement services.

In the implementation phase, HFAs will use their own reserve funds as well as those of the housing projects to establish relationships with service providers. It is expected that a combination of client fees and housing-based reserve subsidies will pay for services requested by the residents.

Planning grants under the first phase of the program were awarded to the following HFAs:

- $144,807 to the Colorado Housing and Financing Authority, Denver;
- $49,598 to the Illinois Housing Development Authority, Chicago;
- $88,517 to the Maine State Housing Authority, Augusta;
- $204,000 to the Massachusetts Housing Finance Agency, Boston;
- $62,697 to the New Hampshire Housing Finance Authority, Manchester;
- $182,935 to the New Jersey Housing and Mortgage Finance Agency, Trenton;
- $179,874 to the Pennsylvania Housing Finance Agency, Harrisburg;
- $107,669 to the Rhode Island Housing and Mortgage Finance Corp., Providence;
- $64,786 to the Vermont Housing Finance Agency, Burlington; and
- $71,620 to Virginia Housing Development Authority, Richmond.

The program is directed by James J. Callahan, Jr., PhD, who also directs the Policy Center on Aging at Brandeis University in Waltham, Mass. The Robert Wood Johnson Foundation was established as a national philanthropy in 1972. Since then, it has awarded more than $906 million in grants to improve health care in the United States. For further information, contact the RWJ Foundation, P.O. Box 2316, Princeton, NJ 08543-2316. Tel: (609) 452-8701.

A Recent Increase of Breastfeeding Duration in Jakarta, Indonesia

M. Riduan Joesoef, MD, PhD, Joseph L. Annest, PhD, and B. Utomo, MD, MPH

Abstract: Comparison of breastfeeding practices from two similar surveys conducted in Jakarta, Indonesia shows an increase in breastfeeding duration from 14.4 months in 1976 to 19.8 months in 1983. This increase was predominantly among noneducated women (20.3 months among noneducated women versus 0.9 months among women with greater than elementary education). Among working women breastfeeding duration declined slightly (1.1 months). Unlike industrialized countries where increases in breastfeeding have occurred initially among the higher socioeconomic groups, recent increases in Jakarta have occurred initially among the lower socioeconomic groups. If breastfeeding practices among working or better educated women who delivered mostly in hospitals or clinics are to be improved, the breastfeeding promotion programs should be targeted to these groups. (*Am J Public Health* 1989; 79:36–38.)

Introduction

Until recently, breastfeeding has been declining in most developing countries, especially in cities and peripheral urban areas.[1–4] The decline in breastfeeding practices has had a detrimental impact on infant health and survival.[5] As a result, many developing countries where infant health and survival are a major health problem have launched national programs to promote breastfeeding.[6]

Breastfeeding practices are usually examined by a single cross-sectional survey at one point in time. Obtaining equivalent surveys on breastfeeding practices at two points in time is difficult, particularly in cities where breastfeeding patterns are changing most rapidly. Recently, however, two studies—one in Malaysia,[7] the other in the City of Sao Paulo, Brazil[8]—evaluated breastfeeding trends and found a revival of breastfeeding practices.

In Indonesia the National Commission on Breastfeeding, a nongovernmental body, was founded in 1977 to coordinate a national program to promote breastfeeding. Two similar household surveys conducted in 1976 and 1983 provided the opportunity to examine changes in breastfeeding practices. In this report, we examined changes in breastfeeding practices in Jakarta, a city with a population of more than 6.5 million in 1980.

Methods

We used data from the two large household surveys conducted in 1976 (Indonesia Fertility Survey) and in 1983 (Indonesia Contraceptive Prevalence Survey). Because only Jakarta was covered by both surveys, we restricted our comparison of breastfeeding practices to Jakarta. Both surveys were based on a probability sample designed to be approximately self-weighting; clusters of households were randomly selected, and in each household all ever-married women aged less than 50 years were enumerated. The principal reports of the two surveys contain a detailed methodological description.[9,10]

In both surveys, a similar questionnaire design was used in which interviewers asked questions about the initiation and duration of breastfeeding and whether the child was currently breastfeeding. In the 1983 survey, breastfeeding questions were asked only to woman whose last living child was 3 years of age or younger. These breastfeeding questions referred only to the woman's last (most recent) live birth, not to her "next-to-last" live birth or other births, i.e., breastfeeding in her current birth interval.[11] In the 1976 survey, breastfeeding referred to the woman's last (most recent) live birth, regardless of the child age. To make the two surveys comparable in terms of breastfeeding definition, for the 1976 survey we restricted our analysis to the women whose last living child aged 3 years or younger at the time of the survey.

In this study, breastfeeding refers to the period from birth to complete cessation of breastfeeding, regardless of supplemental foods. Life-table techniques were used to calculate the median duration of breastfeeding and the proportion of women who were still breastfeeding their last living child at various durations of postpartum.[12] We used SPSS[x] (Survival Procedure) software package to construct the life-table.[13] The following variables and categories were examined: mother's work status at the time of the survey (yes, no); mother's and father's education (no school, ≤ elementary, > elementary); number of living children (< 3, ≥ 3); mother's age (< 30 years, ≥ 30 years); and desire for more children (yes, no).

Results

The total percentage of women who initiated breastfeeding was high and stable for both surveys—98 per cent in 1983 and 93 per cent in 1976 (Table 1). The rates of initiation were high and slightly higher in the 1983 survey across all factors examined (Table 1).

In both surveys the proportion of women still breastfeeding during the first month of postpartum was also high (0.96 in 1983 and 0.98 in 1976). After the first month, the proportion of women breastfeeding declined in a similar pattern up to six months for both surveys (Figure 1). After six months, the proportion of women breastfeeding declined less rapidly in 1983 than in 1976.

Overall, the median duration of breastfeeding increased substantially from 14.4 months in 1976 to 19.8 months in 1983 (Table 2). The change in breastfeeding duration varied across sociodemographic groups with the lowest educated group having the largest increase (Table 2). For mothers with no school education the median duration increased substantially from 15.7 months in 1976 to 36.0 months in 1983, but for mothers with education greater than elementary the median duration increased only from 13.1 months to 14.0 months. A similar pattern was seen for father's education. For mothers who did not work at the time of the survey, the median duration increased from 13.8 months to 20.3 months, and for

mothers who worked, the duration decreased slightly from 16.4 months to 15.3 months (Table 2).

Discussion

In this investigation, we found an increase in breastfeeding duration in Jakarta during the study period from 1976 to 1983. The increase was the highest among noneducated women. Essentially no changes were seen for women with greater than elementary education and for working women. The rates of breastfeeding initiation were practically unchanged across various sociodemographic groups in both surveys. Consistent with previous studies, the rates of breastfeeding initiation and duration of breastfeeding were high.[14–16] Bracher and Santon[14] who studied the breastfeeding practices in Central Java between 1976 to 1978 found that "fully two-fifths of children can be expected to be unweaned by the longest duration recorded in this study" (29 months).

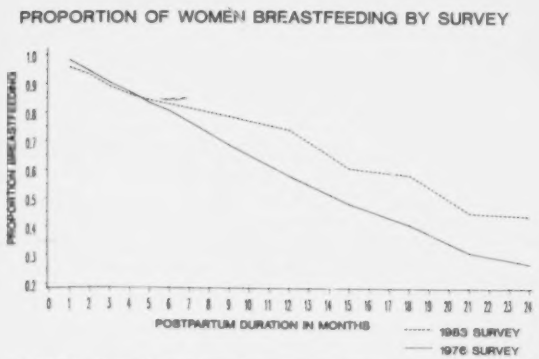

FIGURE 1—Proportion of Women Breastfeeding by Survey, Jakarta, Indonesia, 1976 and 1983

In another study in 1973, Djumadias and Mastaitella found that in South Sulawesi (one of the provinces in Indonesia) 38 per cent of the women breastfed their children between two and three years.[16] These total breastfeeding durations are in agreement with the total breastfeeding duration of the present study.

The increase in breastfeeding duration is not explained by differences in the study population, sampling, or questionnaire design. The sociodemographic characteristics of the two study populations, sampling, and questionnaire design for the two surveys were similar. Some effect of recall bias, however, or some other form of nonsampling error cannot be ruled out. Because the degree of the recall bias was proportional to the length of time the women had to recall the information, limiting our analysis to breastfeeding information from the last live child who was born three years before interview would tend to minimize the recall bias. As a secondary analysis, we evaluated breastfeeding duration only for mothers who were still breastfeeding at the time of interview (those least affected by recall bias); findings were similar. In both surveys we found insignificant, similar heaping of breastfeeding duration at 12, 18, and 24 months postpartum. Thus, we believe that the increase in breastfeeding duration is not an artifact of reporting bias, but a true reflection of a change in breastfeeding duration. These changes may apply to other major Indonesia cities (cities that were surveyed in 1983) because the breastfeeding patterns for these cities and Jakarta were similar.[17]

The vigorous efforts by the National Family Planning Coordinating Board to reduce fertility also might have had an impact on differences in breastfeeding duration between the two surveys. McNicoll and Singarimbun stated that modern contraception was responsible for fertility reduction in Indonesia.[18] Bracher and Santon who studied the breastfeeding practices in Central Java between 1976 to 1978 found that two-fifths of the mothers who weaned their children were known to be pregnant.[14] Fertility reduction might prolong breastfeeding duration because mothers who were breastfeeding might have weaned their children when they became

pregnant. Comparison of the rates of current pregnancy between the two surveys supports this hypothesis. The rate was 15.7 per cent in 1976 and 9.3 per cent in 1983.

The national breastfeeding promotion programs, which were started in 1977, might have had an impact on breastfeeding duration. However, we believe that these programs have failed to convey the correct messages or have inadequately reached the working or better educated women who delivered mostly in hospitals or clinics.[17] A recent survey of rooming-in and breastfeeding management in teaching hospitals of Jakarta and other major Indonesian cities supports our belief.[19] Only 50 per cent of mothers who delivered their babies in these hospitals chose "rooming-in" with the babies. No mothers and very few health care providers mentioned frequent suckling, relaxation, and emotional support as important determinants for prolonged breastfeeding. In addition, this hospital survey found three of 15 hospitals with posters promoting infant formula, and at least one hospital administrator in each of the cities in the hospital survey admitted that mothers in their hospital did receive bottle-milk samples.

According to the World Health Organization proposed model of breastfeeding practices, the elite, better educated people will lead the breastfeeding revival, followed by the poor urban people as has been observed in the United States and Sao Paulo, Brazil.[5,8] Contrary to this model, in Jakarta, the less educated women led the breastfeeding revival. These findings are similar to those found in the study conducted in the neighboring country of Malaysia, where cultural and religious values are similar to those in Indonesia.[7] The increase in Malaysia, however, was not in the duration but in the initiation of breastfeeding.

ACKNOWLEDGMENTS

We wish to thank the staffs from the World Fertility Survey and the Central Bureau of Statistics who provided us with the 1976 survey tapes.

Patient Education Conference on Arthritis Scheduled for March 1989

The National Arthritis Advisory Board and the National Institute of Arthritis and Musculoskeletal and Skin Diseases will sponsor a conference, "Financing Patient Education in Arthritis Musculoskeletal and Skin Diseases," March 23–24, 1989 in Atlanta, Georgia. The conference will address such topics as the cost-effectiveness of patient education in chronic disease, assuring the quality of patient education, and various perspectives on financing and third-party reimbursement of patient education. In addition, ongoing programs that might serve as models will be presented, and participants will meet in small groups to discuss future activities and plans that might be undertaken on a regional basis.

The goals of the conference are:

- To present what is known about the clinical and fiscal efficacy of patient education in arthritis and musculoskeletal and skin diseases,
- To document what is known and identify areas requiring further investigation, and
- To stimulate interest in obtaining third-party reimbursement for patient education in arthritis and musculoskeletal and skin diseases.

Cryptosporidiosis and Surface Water

Margaret M. Gallaher, MD, Joy L. Herndon, MS, Linda Jean Nims, MS, Charles R. Sterling, PhD, Debra J. Grabowski, MS, RS, and Harry F. Hull, MD

Abstract: In the period July through October, 1986, 78 laboratory-confirmed cases of cryptosporidiosis were identified in New Mexico. To determine possible risk factors for development of this disease, we conducted a case-control study: 24 case-patients and 46 neighborhood controls were interviewed. Seventeen (71 per cent) of the 24 case-patients were females, seven (29%) were males; their ages ranged from 4 months to 44 years, median 3 years. There was a strong association between drinking surface water and illness: five of the 24 case-patients, but none of the 46 controls drank untreated surface water. Among children, illness was also associated with attending a day care center where other children were ill (odds ratio = 13.1). (*Am J Public Health* 1989; 79:39–42.)

Introduction

Cryptosporidium, first recognized as a cause of diarrhea in humans in 1976,[1] has become known as a common cause of diarrhea worldwide.[2,3] No effective therapy is known; the diarrhea is often prolonged and accompanied by weight loss. In immunocompromised persons, cryptosporidiosis can cause a life-threatening dehydration.

Cryptosporidium can be transmitted through contact with animals, especially cattle and sheep,[4] through person-to-person contact, especially in day care centers,[5] and through a contaminated community water source.[6] In several reported outbreaks, the source of the infection was unknown.[7,8]

In 1984, 24 cases of cryptosporidiosis were reported to the New Mexico Office of Epidemiology, 13 of them were associated with two day care centers. In 1985, 24 cases were reported. In July 1986, a cluster of 20 cases of cryptosporidiosis was recognized in Bernalillo County (the city of Albuquerque). Because these cases did not appear to be related and the source of infection was unclear, a case-control study to evaluate potential risk factors for illness was conducted.

Methods

Since February 1984, all stool samples submitted to the New Mexico Health and Environment Department's Scientific Laboratory Division for ova and parasite testing have been examined for *Cryptosporidium*. Stool samples are concentrated using a formalin-ethyl acetate technique. A heat-fixed fecal smear is stained with Kinyoun modified acid-fast stain[9] and counterstained with Loeffler methylene blue. The specimen is then examined under a light microscope for the presence of *Cryptosporidium* oocysts.

In August 1986, the Office of Epidemiology sent a letter to primary care physicians in Bernalillo County, alerting them to the cluster of cases, reviewing the symptoms and diagnosis of cryptosporidiosis, and requesting that stool samples be sent if cryptosporidiosis was suspected.

A case-patient was defined as a Bernalillo County resident with laboratory-confirmed cryptosporidiosis reported to the Office of Epidemiology between July 1 and October 1, 1986. If more than one person with laboratory-confirmed cryptosporidiosis was identified within a household or day care group, only the one with the earliest onset of symptoms was included in the study.

Controls were matched for age, sex, and neighborhood using a reverse telephone directory. The home of the case-patient was identified in the directory. The homes listed on either side of the case-patient were contacted by telephone alternately until suitable controls were identified. Case-patients 10 years old or younger were matched within two years of age, and those over 10 years were matched within five years of age. A control could not have had diarrhea in the four weeks before the onset of disease in the case-patient to which he/she was matched. Twenty-two of the 24 index cases were matched with two controls each. Two index cases were matched with only one control.

A standard questionnaire, administered via telephone to both case-patients and controls, requested information on size of household, day care attendance or contact, travel, surface water exposure, pets and domestic animal exposure during the four weeks before onset of illness in the case-patient.

Two surface water samples were collected on October 27, 1986 from a lake in southern New Mexico and a lake in Arizona where three of the case-patients had been exposed to surface water. These samples were tested for *Cryptosporidium* and *Giardia* using a fluorescent labeled monoclonal antibody technique.[10,11]

Using the matched triplets or pairs, we calculated Mantel-Haentzel chi-square, odds ratios (OR), and 95% confidence intervals (CI) and fitted a conditional logistic regression to determine which variables were independently associated with infection with *Cryptosporidium*.

Results

Of the 56 laboratory-confirmed cases of cryptosporidiosis in Bernalillo County reported between July 1 and October 1, 26 met the definition of a case-patient. Two (8 percent) of the cases were lost to follow up (a 1-year-old female who attended a day care center and a 43-year-old female). Of the 30 cases excluded from the study, two were patients with acquired immune deficiency syndrome who died during the course of the study, 10 were household

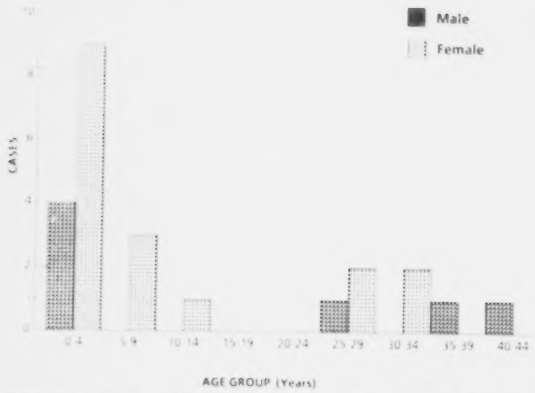

FIGURE 1—Cryptosporidiosis, by Age Group and Sex, New Mexico, 1986

contacts of case-patients, and 18 were day care contacts of case-patients.

The 24 remaining case-patients ranged in age from 4 months to 44 years with a median age of 3 years. Figure 1 shows the age and sex distribution of the index cases. Seventeen of the cases were 10 years of age or younger; 13 of whom were females; 17 of all 24 cases were female. Thirteen (54 per cent) of the case-patients were White and 11 (46 per cent) were Hispanic. Controls showed similar demographic characteristics.

Case-patients had onset of symptoms from May 28 to September 2, 1986 (Figure 2). The duration of symptoms ranged from five to 60 days with a median of 21 days. The most frequent symptom (Table 1) was diarrhea followed by flatulence and abdominal pain.

Matched set analysis identified two possible sources of infection: surface water (rivers, lakes and streams) and day care centers (Table 2). Five case-patients drank untreated surface water, two in Mexico, and three in southern Colorado and New Mexico; none of the controls drank surface water. Case-patients reported more swimming in surface water in

TABLE 1—Frequency of Reported Symptoms of Cryptosporidiosis, New Mexico, 1986 (N = 24)

Symptom	No.	%
Diarrhea	23	96
Flatulence	20	79
Abdominal Pain	17	67
Nausea	15	58
Fever	13	54
Vomiting	12	46
Abdominal distention	12	46

the four weeks prior to illness. The time between exposure to surface water (swimming or drinking) and onset of illness ranged from four to 21 days with a median of seven days. Fourteen (82 per cent) of 17 household members with exposures to surface water similar to the case-patients also became ill with diarrhea. These household members became ill within two to seven days of the onset of illness in the case-patient.

Case-patients were substantially more likely to attend a day care center where other children were ill with diarrhea than were their matched controls (Table 2). Attendance at day care centers where no other children were ill was not related to risk.

The logistic regression model for multivariate analysis included all variables except drinking surface water, which did not vary. Infection was associated with swimming in surface water, attending a day care center, camping, and having a pet which was less than six months of age or was ill, with odds ratios all greater than 3.0. Having a pet over six months of age was associated with a decreased risk of disease. All of these estimates were unstable, with 95% confidence limits including 1.0.

Among the 24 case-patients, eight were exposed to surface water, eight were day care center attendees or employees, six were household contacts of a day care center attendee, and eight had young and/or ill pets. Four had none of these exposures.

The surface water samples from New Mexico and Arizona where cases had been exposed did not yield *Cryptosporidium* or *Giardia* on testing.

Two of the 24 index cases were coinfected with *Giardia*.

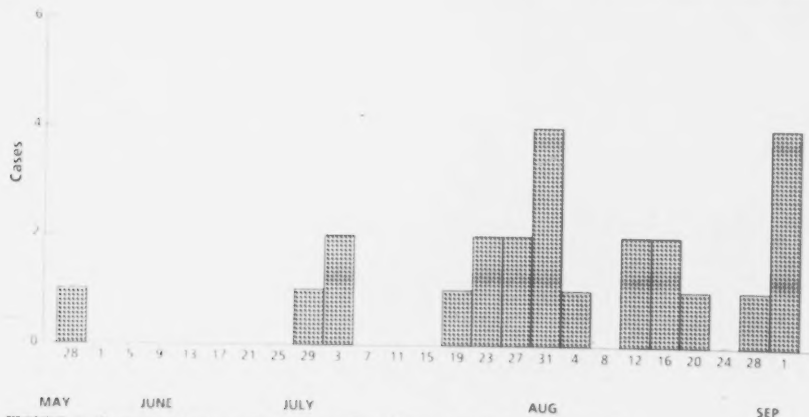

FIGURE 2—Cryptosporidiosis, by Date of Onset, New Mexico, May 28–September 4, 1986

TABLE 2—Exposures Associated with Cryptosporidiosis

Exposure	No. of Cases Exposed	No. of controls exposed			Odds Ratio	95% Confidence Interval
		0	1	2		
Drink surface water	0	17 (2)	0	0	00	2.44, 00
	1	5	0	0		
Swim in surface water	0	14	3	0	3.7	1.02, 13.5
	1	4 (2)	1	0		
Attend a day care center where other children were ill	0	15 (1)	1	0	13.1	2.58, 66.4

	1	5 (1)	1	0		

Numbers in parentheses represent cases with only one control.

One of them attended a day care center. The other had no apparent risk factors for cryptosporidiosis or giardiasis.

Discussion

Person-to-person transmission of cryptosporidiosis is well recognized, especially in day care centers.[5,12] Lack of hygiene and frequent mouthing of objects among diapered babies and toddlers can lead to the rapid spread of this and other enteric infections in day care centers and homes.[13] This study confirmed the association between attending a day care center, especially where other children are ill, and cryptosporidiosis.

Cryptosporidiosis has also been found to be a cause of traveler's diarrhea, particularly in people traveling to less developed countries.[2,14] In this study, two (8 per cent) of the index cases had recently traveled to Mexico; both of these case-patients also drank untreated surface water in Mexico.

Although puppies and kittens have been shown to excrete *Cryptosporidium*,[4] these pets have not previously been demonstrated to transmit cryptosporidiosis to humans. Contact with a young and/or ill pet was associated with an increased risk of disease in this study, but the numbers are too small to be convincing. Nevertheless, this observation is in keeping with what is known of cryptosporidiosis in domestic animals: young animals contract cryptosporidiosis more often than older animals, and the severity and duration of illness is inversely related to the age of the animal.[1,15]

This study suggests for the first time that drinking surface water may be a mode of transmission of cryptosporidiosis in the United States. This is feasible since waterborne cryptosporidiosis has been previously demonstrated in a community in Texas due to a contaminated artesian well.[6] The plausibility of waterborne transmission is increased by the time relationship between exposure to surface water and onset of illness. The median incubation period of seven days in those case-patients exposed to surface water is consistent with what is known of the incubation period for cryptosporidiosis.[16]

Cryptosporidium sp. has been found in a broad variety of both domestic and wild animals. Cattle and sheep appear to be important hosts, but mice, snakes, rabbits, and deer have also been found to excrete the organism.[4,15] Much of the recreational water in New Mexico and other western states drains land which has multiple uses including the grazing of livestock. Livestock could contaminate surface water with *Cryptosporidium* by direct deposit of feces in the water or via surface runoff washing animal feces into the water. Similarly, contamination of the water by wild animal feces might also play an important role. New Mexico received heavier than normal rainfall during the summer months of 1986, a factor which may have promoted contamination of surface water.

The finding of an elevated risk of cryptosporidiosis among persons who had recreational contact with, but did not drink surface water, supports waterborne transmission of the disease. Recreational surface water contact, specifically swimming, has been shown to be a risk factor for other enteric infections.[17,18] Swimmers become infected by swallowing small amounts of contaminated water, especially following submersion. The infective dose of *Cryptosporidium* is unknown, but is probably small, because of the organism's ability to complete its life cycle in a single host and to reinitiate the developmental cycle in that host.[4] A small infective dose for cryptosporidiosis would facilitate transmission by water contact without frank water consumption.

Our studies of surface water in New Mexico were limited in scope, but failed to demonstrate the presence of *Cryptosporidium*. These studies were done two months after the outbreak and probably represent a failure to detect intermittent, low-level, or seasonal contamination. Additionally, the samples were taken from a large lake and it was difficult to determine the exact site of exposure. Studies of surface water conducted in Arizona showed that there was widespread contamination of streams with *Cryptosporidium* during the summer of 1986,[11] but that most of the water sources did not contain *Cryptosporidium* during the fall months.*

Cryptosporidiosis occurs more commonly in summer and fall in these and other data.[3,4] Increased outdoor activity during the summer and early fall with drinking of or swimming in surface water may partially explain the seasonal variation.

Coinfection with *Giardia lamblia* has been found in 2 per cent to 23 per cent of cryptosporidiosis cases in previously described outbreaks[19–21] and 8 per cent in this study. The coincidental occurrence of two parasitic infections suggests a common mode of transmission. Person-to-person transmission of both giardiasis and cryptosporidiosis in day care centers has been well described.[12] Waterborne transmission of giardiasis from surface water is also well known.[22,23] Our

* Unpublished data, CR Sterling, University of Arizona, 1986.

study suggests that waterborne transmission of cryptosporidiosis may explain coinfection with these two parasites, even though neither of the coinfections in this study occurred in persons who had exposure to surface water.

The median duration of diarrhea in the study population was longer than the three to 14 days described by others,[1,17,25] perhaps because patients who had stool samples submitted for ova and parasite examination had diarrhea that lasted longer than three to five days and did not respond to usual symptomatic treatment.

The predominance of young children found here has been seen in other studies, and follows the same pattern seen in domestic animals. In addition, young children are more likely to come to medical attention earlier in the course of a diarrheal illness than adults and more likely to be tested for the cause of their diarrhea. The explanation for the predominance of females seen in this group of children is not clear and may reflect only incomplete case ascertainment.

Further study of the role of surface water in transmission of cryptosporidiosis is clearly needed. Meanwhile, boiling of surface water rather than chemical disinfection may be prudent, since *Cryptosporidium* is resistant to most commonly used chemical disinfectants including chlorine and iodine,[15,24] but oocysts are destroyed by heating above 65°C for 30 minutes.[24] Boiling also destroys other organisms, including *Giardia*, that may be in the water. We also recommend that physicians consider cryptosporidiosis in the differential diagnosis of persons with diarrhea and a history of surface water contact.

ACKNOWLEDGMENTS

The authors wish to thank Kathy Powers, RN, and Judy Knott, RN, for their assistance in this study. A portion of the data described in this paper was accepted for presentation at the annual EIS Conference, Centers for Disease Control, April 6–10, 1987, in Atlanta, Georgia.

New Report Cites Rise in AIDS Funding by Foundations

A new report by The Foundation Center cites a significant increase in private foundation support for AIDS/HIV programs in the past year, with grants awarded by an increasingly diverse group of funders supporting an ever-wider range of programs. *AIDS Funding: A Guide to Giving by Foundations and Charitable Organizations* reports that, of the $51.6 million awarded by more than 150 private foundations since 1983 (including 40 of the top 100 foundations), $31 million has been provided in the period between August 1987–August 1988.

Roughly half of the funds awarded to date have been made by the Robert Wood Johnson Foundation of New Jersey. Only 3 per cent of all larger foundations—those with $1 million or more in assets or $100,000 or more in total giving (roughly 5,000 of the 25,000 foundations in the United States—have as yet awarded AIDS grants.

While 43 private foundations have awarded cumulative total grants of at least $100,000, only six foundations have awarded, in numbers, 15 or more grants for AIDS/HIV. Five foundations now include AIDS-specific funding as a priority interest.

The Foundation Center is located at 79 Fifth Avenue/16th Street, New York, NY 10003. Tel: (212) 620-4230.

A Prospective Follow-Up Study of Cancer Mortality in Relation to Serum DDT

HARLAND AUSTIN, DSc, JULIAN E. KEIL, PhD, AND PHILIP COLE, MD, DrPH

Abstract: Serum DDT and DDE levels were measured in 919 subjects in 1974 and 1975. Two-hundred and nine of the subjects died, including 54 from cancer, during a 10-year prospective follow-up period. There was no relation between either overall mortality or cancer mortality and increasing serum DDT levels. There was weak evidence of a positive relation between respiratory cancer mortality and serum DDT. The literature on DDT and human cancer is reviewed, and it is concluded that the evidence does not support the opinion that DDT is a human carcinogen. (*Am J Public Health* 1989; 79:43–46.)

Introduction

The widespread agricultural use of dichloro-diphenyl-trichloroethane (DDT) in the United States began in about 1945 and increased steadily until about 1960. At that time its use declined slightly because of increased resistance of pests to it. In June 1972, the United States Environmental Protection Agency (EPA) banned all crop uses of DDT. Outside the United States DDT is still used in agriculture, mainly for cotton crops, and for the control of insect-borne diseases, particularly malaria, in tropical countries.[1]

A major reason for the EPA ban of DDT was that it caused cancer in animals. DDT has been reported to induce liver tumors, lymphomas, and lung tumors in mice and liver tumors in some experiments with rats. On the other hand, feeding studies in hamsters were judged as negative; while those with dogs and monkeys are considered inconclusive.[2–4]

Because of recent litigation regarding putative exposure to DDT resulting from environmental contamination in Triana and other parts of northern Alabama, there is considerable public concern regarding the potential carcinogenicity of DDT in humans. There have been few epidemiologic studies of DDT and cancer, but some have reported an excess of lung cancer mortality among men occupationally exposed to DDT.[5,6] This analysis was undertaken, in part, because of this public concern and, in part, because of the suspected association between lung cancer and DDT.

DDT is metabolized very slowly by human beings, so that DDT metabolites are detectable in the fat and sera of people long after exposures end. This paper describes the overall mortality and the cancer mortality experience of a cohort of people whose serum DDT levels were measured in the mid-1970s and who were then followed prospectively for 10 years.

Methods

The study has been described in detail elsewhere.[7,8] In 1960, 2,283 adult residents of Charleston, South Carolina were enrolled in a prospective follow-up study. In 1974 and 1975 an attempt was made to obtain a venous blood sample from the 1,708 survivors of the original cohort (468 White men; 602 White women; 310 Black men, 328 Black women). Blood specimens were obtained for 304 White men, 327 White women, 204 Black men, and 84 Black women and analyzed for p,p′ DDT and p,p′ DDE by gas liquid chromatography using the Dale-Cueto modified method.[9,10] These 919 subjects comprise the cohort reported on here.

The subjects were recalled between 1984 and 1985 by which time 209 (23 per cent) had died. Seven-hundred of the subjects were determined to be alive, while the vital status of 10 was unknown (99 per cent follow-up rate). The cause of death among decedents was classified in two ways. First, the cause of death as listed on the death certificate was coded according to the 9th Revision of the International Classification of Diseases. Additionally, all deaths were reviewed by a medical committee and a cause of death was assigned by them on the basis of all available information. The determination of the medical committee is used to classify cause of death for internal comparisons comparing one group of study subjects with another. To compare study subjects with an external population, the encoded cause of death is used. Discrepancies between the two classifications account for slight differences in the number of cancer deaths in the internal and external analyses.

Statistical Procedures

Total serum DDT among study subjects was estimated by multiplying serum p,p′ DDE (in parts per billion) by 1.114 and adding to this serum, p,p′ DDT (ppb). This accommodated the slight reduction in the molecular weight of DDE after its metabolism from DDT. Since serum p,p′ DDT and p,p′ DDE comprise about 95 per cent of all serum DDT metabolites and isomers,[11] this combination of the two approximates total serum DDT. The distribution of serum DDT was examined among the 919 subjects and divided into terciles. The relative mortality rate (RR) was obtained for the second and third tercile using the lowest tercile as the referent category.

In the internal comparisons below, the relation between serum DDT and mortality is evaluated after adjustment for age, race, gender, years of schooling, and cigarette habit (non-smokers, ex-smokers, and current smokers) through the use of Cox's proportional hazards (PH) model.[12] Indicator variables were used to denote the terciles of DDT. The antilogarithm of the parameters from such a model is inter-

pretable as the RR of the cause of death of interest for persons in the second or third tercile compared with those in the first. Dose-response was evaluated by including the logarithm of serum DDT in a PH model or by assigning scores of 0, 1, and 2 for the first, second, and third terciles, respectively, and including this ordinal exposure variable in a PH model. The logarithm (base 10) of serum DDT was used as the continuous exposure since the distribution of serum DDT is asymmetric. The 10 subjects whose vital status is unknown were considered lost to follow-up at the midpoint of the interval between the date their blood was assayed and January 15, 1985.

As an additional test for association between serum DDT and mortality, the mean of the logarithm of serum DDT was compared for those who had died from all causes or from some specific cause with those who had not. These means were obtained from a multiple linear regression model which included terms for the potential confounders, an indicator variable denoting whether or not the individual had died of that cause, and with the logarithm of serum DDT as the outcome variable.

In addition to the internal analyses described above, the mortality experience of study subjects was compared to that of residents of the United States or of South Carolina. The age- (six 10-year groupings), gender-, and race-specific person-years of observation of subjects were obtained and the corresponding age-gender-race specific cancer mortality rates of the 1980 United States or South Carolina population were applied to those person-years to obtain an expected number of deaths.[13] The observed number of deaths divided by the expected number is the standardized mortality ratio (SMR). The Poisson distribution was used for the purposes of statistical testing and estimation.[14] All P-values in the results section are two-tailed.

Results

The median age of study subjects at the beginning of the follow-up period was 60 years (range: 39 to 89 years). The mean serum DDT level was 48 ppb with a standard deviation of 36 ppb (on the logarithm scale the mean is 1.59 and the standard deviation is 0.30). The mean level of serum DDT was about 6 per cent higher among men than women, and about 14 per cent higher among Blacks than Whites. Serum DDT levels increased with age and were lower among the more educated. The mean DDT levels were slightly lower among current and former cigarette smokers than among nonsmokers.

Internal Mortality Comparisons

The distribution of all deaths and of cancer deaths according to tercile of serum DDT is displayed in Table 1. The slight positive trend in overall mortality with increasing serum DDT is not significant either with the ordinal scale or the continuous logarithm measurement. The adjusted RRs are slightly lower than the unadjusted estimates, principally because of confounding by age and gender. The adjusted mean difference of the logarithm of serum DDT for decedents and the living is 0.025 (95 per cent confidence intervals = −0.02, 0.07).

There is no consistent positive trend in cancer mortality according to serum DDT. The adjusted mean of the logarithm of serum DDT is very slightly lower among persons who died of cancer than it is among those who did not (mean difference = −0.01, 95 per cent CI = −0.08, 0.07).

There is a slight positive trend in respiratory cancer rate according to tercile of serum DDT. However, the point estimates were unstable and the trend test p-values were high. Furthermore, the adjusted mean difference of the logarithm of serum DDT for those who had died of respiratory cancer compared with those who had not is 0.01 (95 per cent CI = −0.12, 0.14). As anticipated, cigarette smoking is a strong determinant of respiratory cancer mortality. The RRs of respiratory cancer for ex-smokers and current smokers compared with non-smokers are 8.3 (0.9, 77) and 24 (3.1, 193), respectively.

TABLE 1—Number of Deaths, Cancer Deaths, and Respiratory Cancer Deaths and the Relative Mortality Rates According to Terciles of Serum DDT

DDT Tercile	Number of Subjects	Person-Years	Deaths	Mortality Rate[a]	Relative Rate[b]
1 (0–31 ppb)	305	2,780	57	2,050	1.0
2 (31–52 ppb)	308	2,722	72	2,645	1.2 (0.8, 1.7)[c]
3 (>52 ppb)	306	2,646	80	3,023	1.2 (0.9, 1.8)
Trend test—ordinal					p = .27
Trend test—continuous					p = .21

DDT Tercile	Cancer Deaths	Mortality Rate[a]	Relative Rate[b]
1	15	540	1.0
2	23	845	1.5 (0.8, 3.0)
3	16	605	0.9 (0.4, 2.0)
Trend test—ordinal			p = .80
Trend test—continuous			p = .96

DDT Tercile	Respiratory Cancer Deaths	Mortality Rate[a]	Relative Rate[b]
1	5	180	1.0
2	7	257	1.5 (0.5, 4.9)
3	7	265	1.8 (0.5, 6.2)
Trend test—ordinal			p = 0.34
Trend test—continuous			p = 0.77

[a]Per 100,000 person-years.
[b]All relative rates are adjusted for age, gender, race, years of schooling, and cigarette habit.
[c]95% confidence intervals shown in parentheses.

TABLE 2—The Number of Observed Deaths, Cancer Deaths, and Respiratory Cancer Deaths and the Standardized Mortality Ratios

Referent Experience	All Deaths			Cancer Deaths			Respiratory Cancer Deaths		
	Observed	SMR	95% CI	Observed	SMR	95% CI	Observed	SMR	95% CI
United States	209	86	(75, 98)	58	98	(74, 126)	21	122	(76, 187)
South Carolina	209	81	(70, 93)	58	104	(79, 134)	21	124	(77, 189)

Seventeen persons died from cancer of the gastrointestinal system. There is a slight inverse relation between gastrointestinal cancer mortality and the logarithm of serum DDT. There were 18 other cancer deaths. No specific site included a number of deaths sufficient to permit a separate analysis. The RRs of all these other cancers for the second and third terciles compared with the first are 1.0 (0.3, 3.1) and 0.5 (0.1, 2.0), respectively.

External Mortality Analyses

The number of deaths and the SMRs for all causes, for cancer, and for respiratory cancer are displayed in Table 2. The overall mortality experience of study subjects was significantly lower than that of comparable individuals in the general population. The overall cancer mortality rate of study subjects was similar to that of the population of the United States and of South Carolina. On the other hand, the SMR for respiratory cancer mortality rate is higher, but not statistically significantly so, among study subjects.

Discussion

This study has a number of strengths for the purpose of evaluating the relation between DDT and cancer mortality, and at least one limitation—its small size. Strengths are that the follow-up was nearly complete and that the ascertainment and classification of cause of death was done without knowledge of the subjects' DDT levels. Furthermore, serum DDT was measured at the beginning of the follow-up period and so is not subject to distortion because of the presence of disease. Thus, the ascertainment of the outcome and the classification of the exposure are free of bias.

The exposure to DDT of this study population began in the late 1940s when it was used for mosquito control, in household pesticides, and for control of agricultural pests. Body burdens of DDT probably resulted from absorption through the skin and lungs and by ingestion. Subjects probably had been exposed chronically to DDT for at least 25 years by 1975, so that a reasonably long induction period would have elapsed.

Our subjects were not selected because of high DDT exposures, but their serum DDT levels were generally higher than among other comparable persons in the southern region. That is, if the age-gender-race structure of the study subjects is applied to the corresponding age-gender-race specific mean values of the logarithm of total serum DDT among southerners in the Second National Health and Nutrition Examination Survey,[11] an expected mean of 1.46 (about 35 ppb) is obtained, whereas the mean among our subjects is 1.59 (about 48 ppb). As another comparison, among 37 decedents aged 55 and over who had been occupationally exposed to pesticides,[17] the mean level of total serum DDT was about 92 ppb whereas among subjects in our upper tercile the mean is about 75 ppb. About 6 per cent of our study subjects had serum DDT levels exceeding 92 ppb. Thus, a number of our subjects apparently had sustained high DDT exposures.

A limitation of the study is that serum DDT and DDE serve as a surrogate measure of past DDT exposures. To the extent that current serum DDT levels are not an accurate indication of past DDT exposures, there will be random misclassification of the exposure and hence a bias in the direction of an absence of association between DDT and cancer. This is of special concern in a negative study such as this, but since DDT is metabolized very slowly, the bias probably is small.[15,16]

The findings of this study do not support the hypothesis that exposure to DDT increases cancer mortality. There is no consistent dose-response between cancer mortality rates and serum DDT levels and the mean level of serum DDT is lower among subjects who had died of cancer than it is among those who had not. Based upon the PH model of cancer mortality with the logarithm of serum DDT as the exposure measure, an upper 95 per cent confidence limit for the increase in cancer mortality sustained by a doubling of serum DDT is about 35 per cent. Thus, although the study includes only 54 cancer deaths, its findings effectively rule out a 50 per cent or more increase in overall cancer mortality attributable to a two-fold increase in serum DDT levels.

The findings with respect to respiratory cancer are less clear. Although there is some evidence of a dose-response relation between serum DDT and respiratory cancer, the point estimates are unstable and the trend is not statistically significant. Furthermore, respiratory cancer risk is lower among subjects in the upper quintile than it is among persons in the middle tercile. The finding that the mean levels of serum DDT are nearly identical for persons who had and had not died of respiratory cancer also does not support a causal interpretation of the finding. Based upon the respiratory cancer PH model it is estimated that a doubling of serum DDT is associated with only an 8 per cent increase in respiratory cancer mortality. On the other hand, the study is too small to exclude moderate increases in respiratory cancer mortality attributable to DDT. The upper 95 per cent confidence limit for excess respiratory cancer mortality associated with a doubling of serum DDT is 83 per cent.

The findings regarding other cancers also suffer from the imprecision resulting from a small study size. Nonetheless, the finding of an inverse relation between cancers of the gastrointestinal tract and cancers from all other sites combined, as well as the observation that no cluster of any particular form of cancer is evident among persons in the upper tercile of serum DDT, provides some assurance that DDT is not related to human cancer. The external SMR analysis indicates that the overall cancer mortality rate in the cohort is about the same as it is in the general population whereas the lung cancer mortality rate may be slightly higher.

Other epidemiologic studies generally do not support the opinion that DDT causes human cancer. In a retrospective follow-up study (RFUS) of pesticide applicators, the overall cancer SMR was 72 with 95 per cent confidence limits of 53 to 96.[18] In the same study the lung cancer SMR was 115 (77,

170), but the risk of lung cancer death was unrelated to duration of employment or the intensity of pesticide exposures. In another RFUS of pesticide applicators,[5] the lung cancer SMR was 135 (94, 189) and there was a consistent dose-response relation between length of licensure as a pesticide applicator and the lung cancer SMRs. In an East German study of agricultural applicators, a two-fold excess of lung cancer was reported.[6] Limitations of these studies are: 1) that these men had been exposed to other chemicals and pesticides so that it is impossible to attribute an excess of lung cancer among them specifically to DDT, and 2) the lack of information on their smoking habits also detracts from a causal interpretation of the findings.

Studies pertaining specifically to DDT do not support the opinion that it is related either to all cancer or to lung cancer mortality. In a follow-up study of workers occupationally exposed to pesticides, there was little difference between the serum DDT levels of persons who developed cancer or respiratory tract cancer as compared to those who did not.[17] In a study of 354 men employed at a plant that manufactured DDT,[19] the SMR for all cancer was 68 (25, 147), while the SMR for respiratory cancer was 125 (34, 321). In another study of workers engaged in the manufacture of DDT,[20] the SMR for all cancer was 99 (82, 119), while the SMR for lung cancer was 149 (68, 282), but in a nested case-control study among these and other workers, the RR of respiratory cancer among men exposed to DDT compared with those not so exposed was 0.74 (95% CI = 0.2 to 2.4, our estimate), while the RR of respiratory cancer pertaining to exposure to inorganic bromides was 7.0 (95% CI: 1.5 to 33, our estimate). This observation suggests that the excess of respiratory cancer observed among these DDT workers may have been due to some exposure other than DDT.

Higginson recently reviewed the epidemiologic evidence pertaining to DDT and cancer and concluded that DDT has had no significant impact on human cancer.[21] The present study supports this opinion. Nonetheless our findings with respect to respiratory cancer are not reassuring. On the one hand, there is a weak and not entirely consistent dose-response relation between serum DDT levels and respiratory cancer mortality that may be due to chance. On the other hand, previous epidemiologic studies have implicated pesticides (but not specifically DDT) as a cause of human lung cancer. Unfortunately, the issue of whether or not DDT is a weak lung carcinogen, or is associated with an increased risk of cancer of some rare site, can be resolved only in a study much larger than the present one.

Kellogg Fellowships Available for Clinicians

New York University's Advanced Management Program for Clinicians invites applications from outstanding health care professionals interested in the development of management skills. Kellogg Fellowships covering partial tuition costs are available for physicians, dentists, nurses, social workers, and other health professionals holding advanced degrees. Fellows may pursue full-time of part-time study leading to a master of Science Degree in Management or an Advanced Professional Certificate.

For additional information contact Greg Thiel, Advanced Management Program for Clinicians, Graduate School of Public Administration, New York University, 738 Tisch Hall, 40 West 4th Street, NY, NY 10003. Telephone (212) 998-7460 or 7445.

A Birth Cohort Analysis of Dental Contact among Elderly Americans

FREDRIC D. WOLINSKY, PHD, AND CONNIE LEA ARNOLD

Abstract: We applied standard cohort and multiple regression techniques to data on the dental utilization rates of 129,191 elderly individuals taken from the 1972, 1973, 1976, 1977, 1980, and 1981 Health Interview Surveys. The results indicate that the marked variation in dental contact rates is a reflection of *cohort succession*, and not a function of aging *per se*. Older cohorts having lower dental contact rates are being replaced by younger cohorts having higher dental contact rates. The dental contact rates of the individual birth cohorts themselves are quite stable over time. The results also indicate that economic barriers (especially liquid assets) have become more important than ever before, especially for the oldest-old. These findings have important implications for public policy about the oral health and health care of elderly Americans. (*Am J Public Health* 1989; 79:47–51.)

Introduction

Dental care for elderly Americans is a significant issue that carries with it a complex web of financial, political, and ethical considerations and implications. Although numerous studies have been published on the epidemiology of oral health problems and the use of dental services among the elderly,[1–11] that literature has been methodologically limited by its reliance on single cross-sectional surveys. The consistently observed age-group differences reflect the effects of cohort differences *and* the aging process, which are inseparable in single, cross-sectional designs.[12–23] Thus, whether the consistently reported age-group decline in dental contact rates indicates aging, cohort, or aging and cohort effects remains unknown. Also unknown are plausible period (i.e., historical) effects on dental services utilization associated with the increasing relative supply of dentists and use of dental hygienists and assistants over the past several decades.[24]

The purpose of this paper is to apply the standard cohort and multiple regression techniques used elsewhere[25–27] to sequential, cross-sectional data pooled from the Health Interview Surveys (HIS) conducted by the National Center for Health Statistics (NCHS).[28,29] This will allow for the separation and examination of the effects of age, period, and cohort on the use of dental services by the elderly.

Methods

Data on 129,191 elderly individuals were taken from the 1972, 1973, 1976, 1977, 1980, and 1981 HISs conducted by the NCHS.[28,29] The HIS is an ongoing annual survey that follows a multistage probability design sampling the noninstitutionalized civilian population of the United States. Eight four-year birth cohorts were identified ranging from 56–59 years of age in 1972 to 92–95 years of age in 1980. These cohorts provide a legitimate opportunity for examining dental contact among the elderly.

Table 1 shows the age composition, cohort designation, per cent having seen a dentist in the past 12 months, and number of cases per cohort at each of the three points in time. Except for compositional changes within aging cohorts and the effects of sampling error, variation in the per cent having seen a dentist can be identified straightforwardly. Age effects may be determined by examining *intra*cohort differences (i.e., by reading diagonally down and to the right). Cohort membership effects may be determined by examining *inter*-cohort changes (i.e., by reading down the columns). Period effects may be determined by comparing the same age group at one point in time with that in another point in time (i.e., by reading across the rows).

There is, however, a confounding problem. Age and cohort effects are both represented in column comparisons, cohort and period effects are both evidenced in row comparisons, and age and period effects are both involved in diagonal comparisons. Thus, the separation of age, period, and cohort effects by visual inspection of standard cohort tables is difficult unless the observed effects are both pronounced and consistent across all comparisons. When this is not the case, more sophisticated statistical techniques must be used to resolve the identification problem.

As informative as the standard cohort analysis of the

data in Table 1 will prove to be, it does not take into consideration the effects of other factors known to affect dental services consumption. Therefore, a second analytic approach is also used. It involves using ordinary least squares in a multiple regression analysis[30,31] to estimate a predictive model of dental contact separately within each column (i.e., time period) of Table 1, and then comparing the observed effects across columns.

The multivariate approach selected is based on Andersen's behavioral model of health services utilization,[32] which has been frequently applied to measures of dental contact.[3,6,11] It defines the use of health services as a function of the predisposing (age, marital status, living arrangements, race, education, and labor force participation), enabling (family income, region of residence, and population density), and need (self-assessed health status and the extent of activity limitations due to health conditions) characteristics of the individual.

The Appendix shows (for all cohorts during 1980–81) the means, standard deviations, and coding algorithms of the indicators used to measure the predisposing, enabling, and need characteristics. The need measures reflect individuals' global health status assessments, and thus are not specific to their need for dental care. Although direct indicators of dental need would be preferable, they are not available for the HISs. Prior multivariate assessments have found specific indicators of dental problems to be statistically unrelated to dental contact[6]; therefore, these indicators would seem appropriate for the present study.

Results

The data in Table 1 indicate three distinct patterns. First, column comparisons reveal consistent, monotonic age-group decreases within each of the pooled surveys. When coupled with the increases in the grand (i.e., within column) means (a short-hand method of partitioning out the confounding effects of aging, which also affect column comparisons), these data suggest a rather strong pattern of change resulting from cohort succession. That is, as new cohorts enter and older cohorts exit the table, the overall percentage of individuals aged 56 to 96 years old who have been to the dentist in the past year increases from 41.2 per cent in 1972–73, to 45.6 per cent in 1976–77, and to 49.2 per cent in 1980–81. Thus, in less than a decade, cohort succession has raised the grand mean of dental contact by a full eight percentage points.

The second pattern involves row comparisons. With two exceptions a consistent monotonic increase is observed across the rows. The exceptions involve the 88–91 and 92–95 year old age groups in 1976–77 and 1980–81. For these age groups about a three or four percentage point drop in dental contact can be observed between columns 2 and 3. In general, however, the row comparisons appear to suggest a period effect that results in higher rates of dental contact over time. Although this interpretation would be consistent with the increasing relative supply of dentists during this same period,[24] it must be remembered that row comparisons also reflect cohort succession, and the column comparisons indicated a clear and consistent pattern of cohort effects. Thus, the row comparisons most likely are artifacts of the effects of cohort succession.

The diagonal comparisons provide the third pattern, although it is not as straightforward. For cohorts 2, 3, 4, and 5 the diagonal (i.e., aging) comparisons indicate relatively stable dental contact rates. Only cohort 1 exhibits a consistent decline, with its contact rate falling by 3.5 percentage points between 1972–73 and 1980–81. The three oldest cohorts (6, 7, and 8) experience either a stable or modest increase between 1972–73 and 1976–77, followed by a larger decline between 1976–77 and 1980–81. Over the full eight-year period, the dental contact rates among these three oldest cohorts decline by between 2.2 and 5.2 percentage points. Thus, the most consistent pattern among the diagonal comparisons is the absence of any aging effects. This provides further support for the dominance of cohort succession effects as the principal explanation of the variation in dental contact rates shown in Table 1.

Table 2 contains the results of the regression analysis. Here age is measured by a set of dummy variables representing each of the cohorts through time. Cohort 1 is the reference category, with its dummy variable omitted from the regression analysis. The interpretation of the cohort dummies within columns of Table 2 is equivalent to the cross-sectional cohort assessment made within column comparisons in Table 1.

The interpretation of the cohort dummies across columns (within rows) in Table 2, however, represents the change in the effect of belonging to a particular cohort as that cohort ages. This is a more pristine distillation of *aging* effects than that shown in the diagonal comparisons of Table 1 for two reasons. First, the aging effects shown here are *net* effects, with the joint effects of the predisposing, enabling, and need characteristics having already been partitioned out. Second, the multiple regression design is such that some of the associated period effects have been residualized to the intercept. Therefore, any differences observed by comparing, for example, the partial, unstandardized regression coefficient of cohort 2 in column 1 with that shown for it in column 2 more closely reflect the effect of cohort 2's having aged four more years. Thus, if the decline in dental contact across age groups reflects the effects of the aging process, there should be a monotonic increase in the absolute value of the coefficients within the rows for each of the cohort dummies. In contrast, if the decline in dental contact across age groups reflects cohort differences, then the coefficients for the cohort dummies should be relatively stable within the rows.

The data in Table 2 clearly show that the partial, unstandardized regression coefficients for the cohort dummies do not exhibit a consistent, monotonic pattern of change. Indeed, the coefficients for cohorts 2, 3, 4, and 5 are virtually isomorphic within rows. Where they do fluctuate, these changes are marginal (i.e., within rows, each coefficient falls within each other coefficient's 95 per cent confidence interval). Thus, at least for these cohorts, the traditionally observed decline across age groups appears to be the result of *cohort succession*, with older cohorts having less dental contact than their younger counterparts.

It is only for cohorts 6, 7, and 8 that significant changes in the coefficients are observed within the rows. This might be taken as an indication that dental contact rates decline with age, but only among the oldest cohorts. If this were the case, however, a consistent, monotonic pattern of change would be expected across both columns for the oldest cohorts. But all of the changes occur between columns 2 and 3, and only for cohorts 6, 7, and 8. Thus, the data indicate statistical interaction between age and period, resulting in a pattern of effects showing a consistent decline in dental contact rates among cohorts who have aged into their eighth decade or beyond between 1976–77 and 1980–81.

TABLE 2—The Unstandardized Regression Coefficients (and their standard errors) Obtained by Predicting the Annual Rate of Dental Contact, for all Cohorts Combined, per Year

Discussion

These analyses have shown that the traditionally observed decline in dental contact rates across age groups is *not* a function of the aging process. Rather, it is a function of *cohort succession*. Generally speaking, dental contact rates are quite stable within birth cohorts as they age from their mid-50s to their mid-90s. Younger cohorts simply have higher rates of dental contact than older cohorts. As a result, the analysis of single, cross-sectional surveys has been somewhat misleading.

The identification of the effects of cohort succession suggests that if the trends observed in the 1970s continue through the 1980s, then by the early 1990s dental contact rates among those aged 56–96 should rise by about another 10 percentage points or so. That would result in three out of five older Americans going to see the dentist at least once a year. Thus, without any programmatic intervention, the oral health care of the elderly should continue to improve. The identification of the cohort succession effects also suggests that dental contact is a lifestyle trait that is relatively stable over the life course. As such, it would seem that oral health education programs targeted at older persons are unlikely to be effective in altering the behavior of those who routinely do *not* see a dentist on an annual basis.

The R^2 values of Table 2 (0.14 to 0.15) are generally consistent with prior studies of dental utilization among elderly Americans. Nevertheless, the low values underscore the fact that far too much oral health behavior remains unexplained. Better measurements, and the inclusion of additional indicators, such as those tapping dental insurance coverage, would seem fruitful for use in future research. Extant studies, however, offer little hope that such modifications will appreciably enhance the R^2 levels.[3,6,11,34]

With the exception of income, the effects of all of the other factors in the behavioral model (besides age) are quite stable over time. Being female, living alone, having more education, living outside of the midwest, living in a major metropolitan area, having more income, and being in good health all increase the likelihood of having seen a dentist in the past year. Being widowed, being a minority, and living on a farm all decrease the likelihood of dental contact. These results are also generally consistent with those of previous assessments.

It is the increasing importance of income over time that warrants further consideration. In 1972–73 the effect of income was such that each $10,000 increment increased the probability of dental contact by about 0.08. By 1980–81 that effect had nearly doubled, increasing the probability by about 0.14. These differences are substantively important. They indicate that economic barriers to dental care not only failed to dissipate, they actually increased considerably during the 1970s.

These cohort analyses have also shown isolated interaction effects. In general, their explanation is both difficult and requires heavy reliance on historical context.[12] These particular interaction effects (resulting in declining rates of dental contact) involved only those birth cohorts who had reached their eighth decade or beyond between 1976–77 and 1980–81. It was precisely during this period that double-digit inflation occurred. It likely affected the oldest-old more than their younger counterparts, because their general economic wealth is substantially lower,[35] and their assets are disproportionately less liquid.[36]

Given that the consumption of dental services is generally viewed as the most discretionary form of health services utilization,[37] it seems quite plausible that the oldest-old may

have been forced to cut back on dental care in order to maintain their consumption patterns of more essential goods and services. And that suggests that economic factors (especially in the form of liquid assets like income) can become (or may already be) critical barriers between elderly Americans and the dental care that they need. As a result, the oral health component of the American health care delivery system is inequitable.

New Technique Saves Blood Usually Lost During Surgery

Researchers at Northwestern Memorial Hospital in Chicago have developed an innovative procedure for retrieving increased amounts of blood usually lost during surgery, thereby reducing the need for transfusions of donor blood. The technique entails recycling blood saved from absorbent sponges used during surgery.

Most hospitals that recycle the patient's own blood (called "autologous") do so by cleansing and reinfusing blood suctioned from the operating field during surgery. In the past, blood-soaked surgical sponges were weighed to help the operating team compute the amount of blood lost during surgery and then thrown away.

Studies have found that suctioning saves almost 50 per cent of the blood usually lost during surgery. However, the Northwestern group—believing that the blood absorbed by the sponges also could be reinfused during surgery—developed a technique of soaking surgical sponges in saline and filtering, washing, and reinfusing red blood cells. The technique was successful in retrieving an additional 40 per cent of red blood cells that would have otherwise been lost.

Because of health concerns about transfusing donor blood, there is a growing interest in using autologous blood to replace that lost during surgery. Many patients give their own blood several weeks before their surgery to ensure a supply for transfusion.

The NMH surgeons first replace lost blood with that retrieved from suctioning and from the sponges before using blood donated by the patient, and finally units donated by others. The sponge and suctioning retrieval systems are used in procedures involving considerable blood loss, such as in orthopedic and cardiac surgery. In the presence of infection or malignancy, however, intraoperatively retrieved autologous blood cannot be used.

Changes in Alcohol-Related Inpatient Care in Stockholm County in Relation to Socioeconomic Status during a Period of Decline in Alcohol Consumption

ANDERS ROMELSJÖ, MD, PHD, AND FINN DIDERICHSEN, MD, PHD

Abstract: Alcohol sales in Stockholm County decreased by 18 per cent from 1976 to 1981. The socioeconomic status of inpatients treated for alcohol psychosis, alcoholism, alcohol intoxication, liver cirrhosis, and pancreatitis was studied by linking data from the National Housing and Population Censuses in 1975 and 1980 with the inpatient care registers for 1976 and 1981. In both years, all rates were highest for people outside the labor market and lowest among white collar employees. The employment rate for those aged 25–44 years and treated in 1981 for alcohol psychosis, alcoholism, and alcohol intoxication—already low in 1975—had drifted further downward by 1980. Total rates of inpatient treatment for alcohol-related diagnoses generally declined but the gap between blue collar workers and white collar workers widened. We conclude that the goal for national alcohol policy, suggested by the WHO—a reduction of per capita consumption—should be combined with additional measures that will reach all social groups. (*Am J Public Health* 1989; 79:52–56.)

Introduction

Alcohol sales in Sweden increased from 4.9 liters of 100 per cent ethanol per inhabitant aged 15 and over in 1954 to a peak of 7.7 liters in 1976, but then decreased to 6.3 liters in 1981.[1,2] Alcohol sales in Stockholm County have exceeded national levels, but have also declined 18 per cent since 1976. Patients hospitalized for alcohol-related medical conditions have declined,[1,2] as well as charges for drunkenness and drunken driving in Stockholm County.[3–5] However, there has been no decline in deaths (both sexes) or hospitalization of women due to alcohol psychosis, alcoholism, and alcohol intoxication up to 1984.[3]

Survey data indicate that since the late 1960s, alcohol consumption has increased most in social class III (mainly blue collar workers), possibly because the increased equalization of disposable income from 1967 to 1981 made alcoholic beverages relatively cheaper for blue collar workers.[6] Surveys since the mid-1970s find that frequent intoxication among military conscripts has been more common among those with a low formal education and that its decline from 1978–79 to 1983–84 has been greater among military conscripts with a higher formal education.[4]

We hypothesized that the difference in rates of alcohol-related inpatient care between the manual and the non-manual workers categories has increased. We therefore measured the socioeconomic distribution of alcohol-related inpatient care during a period of decline in alcohol sales. A second aim was to elucidate social mobility among inpatients treated for alcohol-related problems.

Methods

Study Population

Stockholm County is a metropolitan area with a population of around 1.5 million inhabitants in 1975 as well as in 1980. At least 97 per cent of all discharges from hospitals in Stockholm County have been registered in the Inpatient Care Register (ICR),[7] making the ICR valuable for epidemiological studies. The Maria Clinic, which accounts for about one-third of all discharges under the diagnosis of alcoholism in the county, is not included in the ICR. At least 95 per cent of the discharges at the Maria Clinic concern patients living in its geographically limited catchment area.

In Sweden, Population and Housing Censuses have taken place every fifth year. The censuses of 1975 (FoB75) and 1980 (FoB80) were compulsory,[8,9] with a non-response rate less than 1 per cent. The definitions of the variables used in this study from the two censuses were essentially identical.[9] A tape was produced by the National Board of Health and Welfare by linking data in FoB75 for Stockholm County with the ICR for 1976 with the aid of the personal identity number which every Swedish citizen has been assigned.[10] The same procedure was performed with FoB80 and the ICR for 1981.

Diagnoses and Social Variables

We studied alcohol psychosis, alcoholism, alcohol intoxication, and the closely alcohol-related somatic diseases of liver cirrhosis and pancreatitis,[11] pooling data for the first three diagnoses because they overlap,[12] and abbreviated them to "AAA" in this report. Within a specific diagnostic category an individual discharged more than once has been counted only once, but one individual could be an inpatient in each of the three diagnostic categories. The study has been restricted to individuals 15–64 years of age for "AAA" and to individuals 25–64 years of age for the latter two categories; each sex has been studied separately. We grouped occupations on the basis of the most detailed level available in both censuses,[13,14] reaching a 90 per cent agreement with the new socioeconomic classification in FoB80. The categories were: manual (blue-collar) workers; non-manual employees, lower level; non-manual employees, intermediate and higher level, including self-employed persons; disability pensioners; house-wives; and "others" (unemployed, employed persons who were on sick leave or other leave since January 1, 1975 or January 1, 1980; those undergoing vocational rehabilitation; those who had had an occasional job during the year; family workers 15 hours or less). Non-manual employees and self-employed were combined into one category for the calculation of rates. Students and persons employed part time were excluded because numbers were small.

Analyses

We calculated the rates of inpatients in 1976 and in 1981 for the whole population and for each socioeconomic category, using a 5 per cent random sample of the population in Stockholm County for the denominators. The rates and 95 per cent confidence intervals were calculated for 1975 and 1980 after standardization to the age-distribution in 1975 for each sex.[15] Since data on inpatient care for "AAA" did not include the Maria Clinic, we excluded persons living in the catchment area of the Maria Clinic from the denominator for "AAA". We estimated social mobility by comparing socioeconomic category for 1975 and 1980 among the 1981 inpatients aged 25–44 years in 1975 who participated in the 1980 census. Since downward social mobility could be caused by disability and ill health,[16,17] we attempted to measure change from a higher to a lower socioeconomic category between 1975 and 1980. For non-manual employees at an intermediate and higher level, downward drift means a transition to lower level: non-manual work, manual work, disability pension or to the "other" category. Downward drift for a manual worker means a transition to disability pension or to "other".

Results

Persons outside the labor market had the highest rates for all of the alcohol-related diagnoses for both sexes and in both years (Table 1). Rates were higher for men than for women, and for manual workers than non-manual employees. Among male non-manual employees, the rates were higher for those at the lower social level (Figure 1). The changes from 1976 to 1981 varied according to diagnosis (Table 1). Among the employed the decrease was generally greater, or the increase smaller, among non-manual employees than among manual workers in both sexes (Figures 1–2). For both sexes, the rates increased with age (Table 2). The change from 1976 to 1981 also varied with age, with the greatest changes being in younger ages. There was an increase for "AAA" among women.

Figures 3 and 4 show a considerable downward drift for in-patients with "AAA" in all socioeconomic categories. Thirty-four per cent of the male inpatients who were employed in 1975 had become disability pensioners or left the labor market by 1981. The corresponding figure for women was 29 per cent. The percentage becoming disability pensioners or "others" did not generally depend on the patient's 1975 socioeconomic category. (Housewives, students and part-time employees are excluded from the comparisons.)

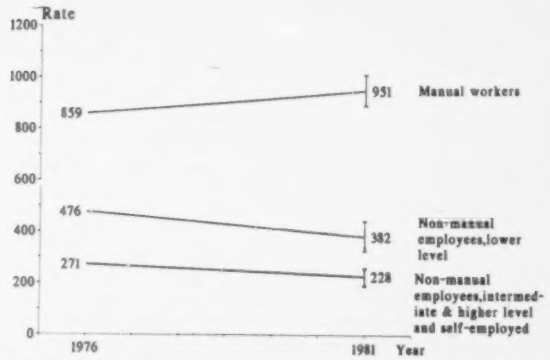

FIGURE 1—Male Inpatients Ages 25–64 Years Treated for Alcohol Psychosis, Alcoholism and Alcohol Intoxication in 1976 and 1981 among Manual Workers and Non-manual Employees (Age-standardized rates per 100,000 men and 95% confidence intervals for standardized rate ratios)

Discussion

Our estimates may reflect biases in the use of diagnostic criteria, selection to inpatient care, criteria for disability pensioning, health-related social mobility, or factors related to working conditions and alcohol availability.

The Use of Diagnostic Criteria—We issued a short questionnaire to the head physicians of all departments of internal medicine, surgery, orthopedics, psychiatry, and

alcoholic diseases in the county, asking for any changes in criteria during 1973–83 for the diagnoses under study. According to the answers from the responding 75 per cent, there had been no such changes. There may have been some social bias in the use of the diagnosis "alcoholism" (and the related diagnoses "alcohol psychosis" and "alcohol intoxication"). Common screening tests (not chemical tests) in the United States have been considered to be biased towards the lower social classes,[18] but the similar patterns we observed for "AAA", liver cirrhosis and pancreatitis suggest that such factors have not been important in this study.

Outpatient Treatment—The changes in inpatient treatment between 1976 and 1981 may have been affected by the increase in outpatient visits from 132,000 to 141,000 visits and greater use of sensitizing agents. These factors were discussed in more detail elsewhere.[3] We lack data on the relation to sex, age, and socioeconomic status for most of those factors, but the rate differences between manual workers and non-manual employees could reflect, in part, greater use of outpatient care and treatment facilities by non-manual employees.

Stefansson and Cullberg have reported that a substantial expansion of psychiatric outpatient treatment facilities in two municipalities in Stockholm County in the mid-1970s was followed by a substantial increase in the proportion of the population receiving psychiatric outpatient care including patients with alcoholism.[19] The total consultation rate, related to population size, was greater for patients from social class III, but greatest for social class II. There was a decrease in hospital admissions for all social classes. Data on social class distribution for outpatients and inpatients with alcoholism were not presented. The proportion of all outpatient visits to doctors was roughly the same for all social classes in 1974 and in 1981 in Sweden.[20] Thus, we have no indication of changes in the social pattern of outpatient visits for alcohol-related problems in Stockholm County from 1976 to 1981, but the data are scanty.

Disability Pensions—After new legislation in the beginning of the 1970s it became easier to get a disability pension, and from 1977 on to get disability pension due to alcoholism as a main diagnosis.[21] Alcohol-related diagnoses were thus

artefactually increased among disability pensioners, but the extent of this effect is not clear.

The total number of newly granted temporary or permanent disability pensions in Stockholm County decreased from 9,071 during the period 1973–75 to 7,881 during the period 1978–80, partly because the retirement age was lowered from 67 to 65 years in 1976.[22] We lack data on disability pensioning for alcoholism in Stockholm County, but we have data for Sweden as a whole. The number of newly granted disability pensions in Sweden with alcoholism or alcohol psychosis as the main diagnosis was 18 per cent higher in 1978–80 than in 1974–76 among men and 25 per cent higher among women (Information from Lena Eriksson, the National Social Insurance Board). Less than 5 per cent of all newly granted disability pensions in men and less than 1 per cent in women were due to alcoholism or alcohol psychosis as the main diagnosis in Sweden, during the 1970s. However, many alcoholics receive a disability pension under other main diagnoses.[23,24] The decline in disability pensioning and the small number of disability pensioners with a diagnosis of alcoholism suggest that changes in legislation and routines do not markedly bias a comparison of socioeconomic categories in 1976 with those in 1981.

Health-related Social Mobility—The much higher rates of alcohol-related inpatient care for disability pensioners and "others" can be explained in part by downward social drift of people unable to work due to alcohol-related disabilities.[16,17] Perhaps the educational requirements and experience needed to reach some of the positions in the category of non-manual work also may be more incompatible with alcohol abuse. In a 40-year follow-up of the Core City sample in Boston, Vaillant found a correlation between progressive course for alcohol abusers and membership in social class IV or V and concluded "that low social class does not cause alcoholism as much as severe alcoholism causes low social class."[25]

On the other hand, two Swedish studies suggest the opposite. Öjesjö, Hagnell and Lanke[26] found that the cumulative probability of developing alcoholism for males in the Lundby cohort in Sweden from 1957 to 1972 was roughly twice as high for manual workers as for middle strata. (Data on social class concerned 1957.) Romelsjö and Ågren[27] found that the mortality in Sweden from alcohol psychosis, alcoholism, alcohol intoxication, and liver cirrhosis was higher among manual workers than among other main occupational categories, but highest among disability pensioners and those who had left the labor market. Poikolainen[28] has reported that the relative risk for inpatient care among men aged 25–64 years in Finland during 1970–75 treated for alcohol psychosis, alcoholism, and alcohol intoxication was higher for manual workers than for clerical workers while the relative risk for liver cirrhosis and pancreatitis showed smaller differences between occupational groups.

Working Conditions—The differences in alcoholism among occupations may also reflect differences in the working environment, possibly because occupations with a greater risk of stress and monotony also carry a greater risk of alcohol abuse. Alfredsson, Spetz and Theorell[29] reported such correlations in the same linked data from 1975–76 used in the present study. Other studies have shown an increased risk of alcohol-related problems in specific occupations,[30,31] but it is not clear whether socioeconomic status relates to alcohol availability.

In sum, available data do not indicate any significant bias in the comparison of rates for various categories and for comparisons over time, and differentials between blue collar and white collar workers in alcohol-related disease appear to have widened. Reduced alcohol consumption has been advocated by the World Health Organization[32] and many countries—among them Sweden[33]—as an important goal for national alcohol policy. Our data show that although the decrease in sales and consumption was followed by a general decrease in alcohol-related problems,[1–4] the decreases were far from uniform across social groups. It seems necessary to combine a further reduction in alcohol consumption with additional measures to reach all social groups.[32–34]

Publication Announcement: Child Studies Survey Available

A Survey of Sources for the Study of the History of Child Studies at the Rockefeller Archive Center (86 pp.) is the latest publication in a series of subject surveys of manuscript sources located at the Rockefeller Archive Center. Compiled by archivist Melissa A. Smith, the survey is available free of charge to interested researchers.

Over the past 80 years, American philanthropic foundations have responded to issues ranging from clean milk campaigns to jobs for unemployed youth. These two diverse causes illustrate the scope of these philanthropies' concern for the health, safety, mental and social development of children in American society.

Materials from the Commonwealth Fund, the General Education Board, and the Laura Spelman Rockefeller Memorial collections comprise the bulk of the survey. Other collections represented include those of the Rockefeller Brothers Fund, the Rockefeller Family, the Russell Sage Foundation, and the Bureau of Social Hygiene. The survey lists folder titles, box and folder numbers, and, when available, brief descriptions of the folder contents.

Researchers and institutions who want a copy of the free survey should contact the Director, Rockefeller Archive Center, 15 Dayton Avenue, Pocantico Hills, North Tarrytown, NY 10591-1598; Tel: (914) 631-4505.

A Study of Battered Women Presenting in an Emergency Department

Susan V. McLeer, MD, and Rebecca Anwar, PhD

Abstract: Medical records of female trauma patients were retrospectively reviewed prior to introducing a protocol for enhancing identification of battered women; 5.6 per cent of 359 female trauma patients were identified as having injuries caused by battering; 30 per cent of 412 patients following use of the protocol were so identified. Standardized protocols for identifying battered women among female trauma patients should be instituted in emergency departments. (*Am J Public Health* 1989; 79:65–66.)

Introduction

Awareness of the extent of domestic violence has heightened since the first reports appeared in the literature during the early 1970s.[1–4] Multi-disciplinary systems have evolved to protect victims, reduce violence, and expand resources.[5] Over 700 shelters have been established, and public policies have evolved at local, state, and federal levels. Nonetheless, in a national survey of 2,143 homes, battering was reported by more than 25 per cent of couples.[6] In a Harris poll of 1,793 women in Kentucky, 21 per cent reported being physically abused, with two-thirds of those divorced or separated being battered.[7] Similar findings were reported in Pennsylvania (26 per cent) and Texas (29 per cent).[8,9] Battering appears to be a more frequent event than job-related assaults of police officers.[10,11]

The National Crime Survey (NCS) projected that in 1980 there were 192,000 assaults within families. While these figures of reported crimes are considerably lower than those determined by other studies (estimating 1.8 million[6] to 3–4 million[12] battered women/year), the NCS data, nonetheless, provide a sobering analysis of the annual morbidity associated with domestic violence: 21,000 hospitalizations, 99,800 days of hospitalization, 28,700 emergency department visits, and 39,900 visits to physicians. The total annual health care costs approximate $44,393,700 with indirect costs of 175,500 lost days from paid work.[13]

These estimates do not begin to address the pain and misery associated with chronic victimization, nor the emotional sequelae for children who witness this form of violence. The mortality is significant also with 17 per cent of the nation's homicides occurring within the family, with half of these deaths being secondary to spouse killing a spouse.[14]

Stark and Flitcraft reported that abuse may be the most common cause of injury in women,[15] with more injury episodes than auto accidents, muggings, and rape combined. Flitcraft in an early study of battering developed the following protocol for identifying and classifying battered women.[16]

	Classification of Battered Women
Positive:	**Injury was attributed to spouse or boyfriend in the medical record of the event.**
Probable:	**The record reports that the patient was beaten, kicked, hit, punched, but no personal etiology was noted.**
Suggestive:	**The recorded etiology of the injury did not seem to account adequately for the injury.**
Negative:	**Nothing in report of the injury would raise suspicion that injury was a result of battering.**

Using this classification system, we reviewed the records of all female trauma exclusive of motor vehicle accidents and natural disasters registered in the Emergency Department (ED) of the Medical College of Pennsylvania (MCP) during 1976. Among the women's injuries, 5.6 per cent were classified as positively caused by battering; 10.9 per cent were classified as probable; and 9.2 per cent as suggestive. Since previous reports had indicated that battered women were often times secretive and reluctant to report when injuries were caused by their having been beaten,[2] we designed a pilot study aimed to determine if through the use of a protocol with direct questions about whether injuries were caused by battering, the percentage of battered women identified could be increased.

Methods

A retrospective record review of every fourth case of female trauma (excluding motor vehicles and natural disasters) presenting in the MCP ED during calendar year 1976 was conducted (n = 359). The ED studied was located in the inner city and primarily served a lower socioeconomic, Black population. During the first two weeks of 1977, the triage nurses in the ED were trained in administering a protocol aimed at identifying battered women. The protocol contained questions which elicited a trauma history and directly asked if the women were injured by someone. The protocol took approximately 15 minutes to administer. The majority of women responded readily to posed questions in the protocol and appear relieved that someone had directly asked them how they had been hurt. Those who had been battered were given information regarding community resources available to them. The majority of women who had not been battered did not appear to mind being asked if they had been hit or injured by someone. Following a full year of protocol

utilization, the ED records for every fourth case of female trauma during 1977 were reviewed (n = 412). Cases were classified as positive for battering whenever a woman directly stated that her injuries were caused by her having been beaten by someone with whom she was or had been intimately involved. Equivocal cases, e.g., probable and suggestive, were classified as trauma, etiology unspecified.

Results

The percentage of women identified positive for battering increased from 5.6 per cent to 30 per cent following staff training and institution of the protocol in the ED. The difference in proportion was 24.5 per cent (95 per cent confidence intervals: 19.5, 29.5).

With increased detection, an unexpected but impressive finding regarding the relationship between age and battering was noted with 42 per cent of female trauma cases in the 18–20 year age span being battered; 35 per cent of the women 21–30 years of age were also battered as were 18 per cent of injured women 61 years of age and older (Table 1).

Discussion

In an extensive review of the literature, we were unable to find reports of such high percentages of battered women among female trauma cases.[12,16,18–20] While our data do not reflect community incidence of battering nor the incidence of battered women among female trauma patients presenting in emergency departments other than in the one studied, the data do suggest that by directing staff attention to the identification of battered women through the use of a protocol, one can increase the positive identification of injuries caused by battering. While our findings may have reflected an increase in the community prevalence of spousal assault between 1976 and 1977 or a change in the characteristics of the population using the ED, pooled hospital demographic data suggest that the latter did not occur. The question of an increase in the number of battered women presenting to the ED secondary to a shift in prevalence is not so easily dismissed; however, during 1976 and 1977, there were no major changes in the political, cultural, or socioeconomic climate that were of sufficient magnitude to suggest systematic change in prevalence.

TABLE 1—Battering as a Cause of Female Trauma Presenting in an Emergency Department

Age (years)	Total Female Trauma	Positive Cases	% Battered
18–20	47	20	42
21–30	174	61	35
31–40	77	20	26
41–50	45	11	24
51–60	42	7	17
61+	27	5	18
Total	412	124	30

The finding that 42 per cent of female trauma victims between the ages of 18–20 were positively battered is impressive and raises questions regarding the prevalence of battering among teenage girls, a population for whom community services are not available. Finally, the geriatric population is one characterized by frequent injuries subsequent to accidents. With 18 per cent of injured women over 61 years of age admitting that they were injured secondary to being beaten, it becomes essential to increase professional awareness of the risk in this age group.

Unless ED staff maintain a high index of suspicion for battering among female trauma patients, large numbers will go undetected, hence, untreated. Emergency physicians should institute the use of standardized protocols in order to provide adequate care to this population of women.

Tea and Premenstrual Syndrome in the People's Republic of China

ANNETTE MACKAY ROSSIGNOL, SCD, JIANYI ZHANG, MD, YONGZHOU CHEN, MD, AND ZHENG XIANG, MD

Abstract: We evaluated the hypothesis that tea consumption causes premenstrual syndrome by studying 188 nursing students and tea factory workers in the People's Republic of China via questionnaires distributed in classes (nursing students) or during routine physical examinations (tea factory workers). Analysis of the data revealed that tea consumption is strongly related to the prevalence of premenstrual syndrome and that the effects are dose-dependent. (*Am J Public Health* 1989; 79:67–69.)

Introduction

The causes of premenstrual syndrome are unknown.[1–3] Putative causes include a hormonal imbalance—particularly a deficit of progesterone,[4] dietary deficiencies,[5–8] a diet rich in highly refined sugar products and/or high fat foods, alcohol use, tobacco use, lack of exercise, oral contraceptive use,[9] and consumption of caffeine-containing beverages.[10]

This study was undertaken to assess the relation between consumption of one type of caffeine-containing beverage (tea) and the prevalence of premenstrual syndrome. To prevent confounding by other (putative) causes of premenstrual syndrome, the study was conducted in a population in which the prevalence of these other causes, including consumption of other caffeine-containing beverages, was expected to be low or zero.

Methods

Study Populations

The study was conducted at three sites in the People's Republic of China: 1) a medical university in Shanghai that trains public health nurses; 2) a nursing school in rural, southern China; and 3) a tea factory in rural, southern China. We expected that the consumption of tea would be less frequent among the nursing students than among the tea factory workers.

The study subjects consisted of all female third and fourth year public health nursing students at the medical university in Shanghai, all female students in one class at the nursing school in rural southern China, and all female workers in the tea factory. The average age of the nursing students was 22.3 years (range, 15 to 33 years), and 24.8 years (range, 17 to 35 years) for the tea factory workers. Participation was 100 per cent for each population.

Data Collection and Analysis

A questionnaire was handed out in class to nursing students at each of the two schools. The questionnaire, although translated into Chinese, was identical in pertinent ways to the questionnaire developed by Rossignol,[10] and solicited information about the presence and severity of premenstrual and menstrual symptoms, demographic characteristics, health-related characteristics (for example, alcohol and tobacco use), use of over-the-counter drugs containing caffeine, and consumption of caffeine-containing beverages. The questionnaires were completed in class and returned.

Data from the tea factory workers were collected during a routine physical examination of each worker. The examinations were performed by female physicians who, during the course of the examination, asked the worker the questions about the presence of menstrual and premenstrual symptoms and about health-related habits including caffeine use. Upon completion of the examination, the physician completed a questionnaire for each worker. The questionnaire was identical to those completed by the nursing students except that the questions related to specific symptoms of premenstrual syndrome were omitted.

We estimated the premenstrual syndrome prevalence odds ratio for two levels of average daily consumption of tea: one-half to four drinks, and four-and-one-half to eight drinks. Area of residence (nursing students, tea factory workers) was controlled by stratifying the data into the two categories of residence and obtaining an estimate for a uniform prevalence odds ratio by the method of maximum likelihood. Heterogeneity of the prevalence odds ratio according to residence was evaluated by the likelihood ratio test proposed by Miettinen, as described by Rothman and Boice.[11] Confidence limits for the prevalence odds ratio were based on Miettinen's test-based procedure,[12,13] using the programs of Rothman and Boice.[11]

The level of severity for premenstrual syndrome was determined by each participant in response to a question asking her to assess the overall severity of her symptoms.

Results

Thirty-nine per cent of the nursing students and 77 per cent of the factory workers reported experiencing premenstrual syndrome. Overall, 74 per cent of these women rated their symptoms as mild, 24 per cent as moderate, and 3 per cent as severe. These proportions were similar in each study group. Among the nursing students, the most common symptoms were breast swelling and tenderness, tiredness, and anxiety, affecting 51, 49, and 34 per cent of women with symptoms, respectively.

Tea was the only reported source of caffeine in both study populations.

Table 1 shows the prevalence of premenstrual syndrome and of putative causes and preventives of premenstrual syndrome by study group. The prevalence of each of the putative causes/preventives, except for tea consumption, was either zero or over 90 per cent for each population. For this reason, any observed association between tea consumption and premenstrual syndrome can not be attributable to confounding by any of these factors. Table 2 shows the prevalence odds ratios of premenstrual syndrome according to average daily tea consumption by residence, and controlling for residence in a high or low tea-consuming region (study group). The prevalence odds ratio for 4.5 to 8 drinks

TABLE 2—Prevalence Odds Ratios of Premenstrual Syndrome According to Average Daily Tea Consumption by Residence

Residence (= Study Group)	Average Daily Tea Consumption (Number of Drinks)	Prevalence Odds Ratio of Premenstrual Syndrome (90% Confidence Interval)
Low Tea Consuming (= Nursing Students)	0	1.0
	0.5 to 4	1.4 (0.5, 4.0)
	4.5 to 8	∞ (–)
	0.5 to 8	1.7 (0.6, 4.5)
High Tea Consuming (= Tea Factory Workers)	0	1.0
	0.5 to 4	4.5 (0.9, 21.7)
	4.5 to 8	8.6 (1.7, 42.9)
	0.5 to 8	5.9 (1.4, 25.3)
Both Residences	0	1.0**
	0.5 to 4	2.0 (0.8, 4.7)
	4.5 to 8	9.7 (2.1, 44.5)
	0.5 to 8	2.4 (1.0, 5.6)

**Prevalence odds ratios were estimated controlling for residence in a high or low tea-consuming region (= study group). The $P_{(2)}$-values associated with the likelihood ratio tests evaluating heterogenity of the prevalence odds ratios by residence were 0.29, 0.58, and 0.19 for 0.5 to 4, 4.5 to 8 and 0.5 to 8 drinks of tea per day, respectively. The crude prevalence odds ratios were 3.4 for 0.5 to 4 drinks of tea per day, and 10.0 for 4.5 to 8 drinks of tea per day.

of tea per day were considerably higher than the prevalence odds ratio for 0.5 to 4 drinks per day, consistent with a dose-response relation between tea consumption and premenstrual syndrome.

Discussion

We found a strong association between tea consumption and the prevalence of premenstrual syndrome, particularly for women who consume 4.5 to 8 drinks of tea per day. The effects were similar to the effects reported in a previous study[10] that evaluated the relation between consumption of all caffeine-containing beverages (cola plus coffee plus tea) and the prevalence of premenstrual syndrome. In this previous study, 49 per cent of the caffeine-containing beverages were drinks of cola, 32 per cent were coffee, and only 19 per cent were tea.

In the present study, consumption of tea, especially for the low consumer, typically occurred non-uniformly throughout the week, with pots of tea shared with friends once or twice per week rather than daily. Tea exposure, therefore, varied considerably from day to day, with no exposure on many days and substantially higher exposure (3 to 4 cups of tea) on other days even among low consumers. It is unknown how this pattern of tea consumption may have affected the study findings.

Several factors might account for the observed relation between tea consumption and premenstrual syndrome, including a causal role for total daily fluid consumption (which might be related to average daily tea consumption) or differences in the reproductive histories of the study participants according to the level of tea consumption. None of the commonly suspected, modifiable causes/preventives of pre-

menstrual syndrome, except tea consumption (Table 1), however, is a possible explanation for the study results because none of these other factors varied in frequency according to tea consumption or the presence of premenstrual syndrome. A possible mechanism involving cyclic nucleotides for a causal relation between tea and premenstrual syndrome is provided by Minton.[14,15]

Differences in the Timeliness of Diagnosis, Breast and Cervical Cancer, San Francisco 1974–85

L. DUNCAN SAUNDERS, MB, BCH, PHD

Abstract: Cancer registry data for San Francisco (1974–85) were used to identify women at greater risk of late diagnoses for breast and cervical cancers by age and ethnicity. For breast cancer, Black women were at greater risk for late diagnoses. For cervical cancer, women of all ethnic groups ages 50–69 years and Japanese and Filipino women were at greater risk for late diagnoses. (*Am J Public Health* 1989; 79:69–70.)

Introduction

Survival rates for women with early diagnosis of breast and cervical cancer are considerably better than for those with late diagnosis.[1] There is also substantial evidence that mortality from breast cancer for women over age 50 years can be reduced with a combination of regular breast examination and mammography.[2–4] For women ages 20–70 years there is good evidence, although no randomized controlled trials have been done, that cervical cancer mortality can be reduced by regular cervical pap smears.[5–7]

Despite this, the utilization of screening tests is low. A 1983 national survey found that only 45 per cent and 14 per cent of women ages 50–70 years had had annual physical examinations and mammograms, respectively. Among women ages 20–39, 79 per cent had had pap smears every three years, compared to only 57 per cent of women ages 40–70 years.[8]

Methods

The study uses data collected on San Francisco women diagnosed with breast cancer (ICD-0 1976 Code 174) or cervical cancer (ICD-0 1976 Code 180) between 1974 and 1985 by the San Francisco-Oakland SMSA cancer registry, which identifies approximately 98 per cent of incident cases of cancer occurring in five San Francisco Bay Area counties.[9] The purpose of this analysis was to examine differences in the timeliness of diagnosis of female breast and cervical cancer in different age and ethnic groups.

Based on the ability of screening programs to detect high percentages of breast cancers without nodal involvement,[4] breast cancers were classified as early (in situ and localized stages) or late (regional or remote stages). As regular pap smears can detect a high percentage of cervical cancers before these became invasive,[5] cervical cancers were classified as early (in situ) or late (localized, regional or remote).

Distribution of the timeliness of diagnosis (early and late) by age group (<30, 30–39, 40–49, 50–59, 60–69 years) for these cancer types were calculated for White non-Hispanic, White Hispanic (primarily Mexican American), Black, Chinese, Japanese and Filipino women for the years 1974–85. The upper age limit of 70 years was chosen to follow the National Cancer Institute recommendations of screening for these cancers under the age of 70 years.[10]

Chi square tests for trend were used to examine the association between late diagnosis of breast and cervical cancer with age. To examine ethnic differences in late diagnoses for these cancers odds ratios (with 95% confidence intervals) were calculated for each of the other ethnic groups using White non-Hispanic women as the reference group.

Results

Breast Cancer

We found that 1,568 (43.5 per cent) of the 3,608 breast

cancers diagnosed in women less than 70 years of age were late diagnoses (regional or remote tumors) with no differences in the percentage of late diagnoses by age (range 40.9–44.4 per cent Chi square for trend = 0.15, p = 0.70); this was true for all ethnic groups. Most cases of breast cancer (69.5 per cent) were diagnosed in women ages 50–69 years and therefore most (69.1 per cent) late diagnoses were in this age group. Of the 1,568 late diagnoses, 1,094 (70 per cent) occurred in White non-Hispanic women. Among the ethnic groups, Black women had significantly more late diagnoses than White non-Hispanic women (Table 1). One hundred twenty-eight (64.3 per cent) of the 199 late diagnoses in Black women occurred in women ages 50–69 years.

Cervical Cancer

Of the 2,090 cervical cancers diagnosed in women less than 70 years old, 430 (20.6 per cent) were late diagnoses (localized, regional or remote tumors). In contrast to breast cancer, there is a marked increase with age in the percentage of women with late diagnoses (Table 2). The odds ratio for 60–69 year-old women compared with women less than 30 years old was 20.2 (95 per cent CI = 12.8, 32.0). Two hundred nine (48.6 per cent) of the 430 late diagnoses occurred in White non-Hispanic women. To examine the association between late diagnosis and ethnicity for cervical cancer, directly weighted pooled estimates of odds ratio (and 95 per cent CI) were calculated to adjust for the confounding effect of age.[11] Of the ethnic groups, Japanese and Filipino women had significantly more late diagnoses than White non-Hispanic women (Table 3).

Discussion

Late diagnosis for breast cancer was common for all age groups. However, 69.1 per cent of late diagnoses were in women ≥50 years of age reflecting the higher incidence of breast cancer in these age groups.[12] Black women with breast cancer tend to be from poorer social classes than White women with breast cancer.[13] The later diagnosis of breast cancer in Black women may reflect lack of access to screening mammography services. The National Cancer Institute has recommended that by the year 2000 80 per cent of women aged 50–59 years[10] should have annual breast examination and mammography. Black women 50–69 years of age should be a high priority for screening.

The higher percentage of late diagnoses for cervical cancer among older women may be due to lower cervical pap smear rates in older women.[8] This in turn may be due to the erroneous perception that cervical cancer is largely a disease of younger women. Cervical cancer incidence rates for San Francisco-Oakland SMSA for women 60–69 years of age are, in fact, higher than for all younger age groups.[12] The National Cancer Institute recommends that by the year 2000 90 per cent of women 20–39 years of age and 80 per cent of women 40–69 years of age should have a cervical pap smear every three years. Efforts in this regard in San Francisco should be directed particularly toward women 50 years of age and older and also toward Japanese and Filipino women.

Breast Cancer Incidence in Young Women by Estrogen Receptor Status and Race

JANET L. STANFORD, PHD, RN, AND RAYMOND S. GREENBERG, MD, PHD

Abstract: A population-based study was utilized to calculate breast cancer incidence rates in White and Black women, ages 30 to 54, according to tumor estrogen receptor status. Both racial groups had higher incidence curves for estrogen receptor negative breast cancer between ages 30 and 49. There was an excess of receptor negative cancer in young Black women, an observation that may help explain the racial disparity in breast cancer survival. (*Am J Public Health* 1989; 79:71–73.)

Introduction

Clinical studies suggest that estrogen receptor analysis should be performed on all primary breast cancers because results provide valuable therapeutic and prognostic information.[1] The presence (estrogen receptor positive) or absence (estrogen receptor negative) of specific estrogen binding protein in breast cancer is related to the biologic characteristics of the tumor. Receptor negativity is associated with larger tumor size and more rapidly proliferating tumor tissue.[2,3] Estrogen receptor status also varies according to some breast cancer risk factors, notably age, menstrual status, and race.[4–11] Despite evidence that receptor results are correlated with prognostic and risk variables, we are aware of only one study that has examined the incidence of breast cancer stratified by receptor results and that study was limited to a predominantly Caucasian population.[12] The present report provides incidence rates of estrogen receptor positive and estrogen receptor negative breast cancer separately for White and Black women based on data collected by a population-based cancer registry.

Methods

Data from the Georgia Center for Cancer Statistics, an affiliate of the Surveillance, Epidemiology and End Results (SEER) Program of the National Cancer Institute, were used to estimate breast cancer incidence rates according to estrogen receptor status. All cases of newly diagnosed, pathologically confirmed breast cancer among women 30–54 years of age were identified during the period of December 1980 through December 1982. Estrogen receptor assay results, abstracted from medical records, were available on 82.4 per cent of the 637 breast cancer cases ascertained during the two-year period (Table 1). Overall, two-thirds of the tumor specimens were assayed at the same laboratory, and 98.6 per cent of the samples were assayed by the standard multipoint titration method using dextran-coated charcoal.[7]

TABLE 1—Number of Incident Breast Cancer Cases Diagnosed by Age and Estrogen Receptor Status, Atlanta, Georgia, 1980–82

Age (years)	Total No. Cases	Estrogen Receptor Status			
		Positive	Negative	Borderline	Unknown
30–34	55	15	33	2	5
35–39	114	36	57	1	20
40–44	133	45	62	5	21
45–49	174	58	69	6	41
50–54	161	77	54	5	25
Total	637	231	275	19	112

There were 231 estrogen receptor positive, 275 estrogen receptor negative, and 19 estrogen receptor borderline (i.e., equivocal results) breast cancers. (Estrogen receptor borderline tumors behave clinically like receptor negative tumors[1,2]; these 19 cases were therefore combined with the estrogen receptor negative group.) Women of other races (n = 3) and those with unknown receptor values (n = 112) were excluded from the calculation of incidence rates. The percentage of women with unknown receptor values did not differ by race: Whites, 17.9 per cent; Blacks, 16.9 per cent. Within each race, the percentage of unknown receptor values was greatest for women ages 45–49 years: Whites, 22.5 percent; Blacks, 28.6 per cent; the racial distribution of cases with unknown receptor results (Whites, 78.6 per cent; Blacks, 21.4 per cent) was similar to that of cases included in the analysis (Whites, 77.6 per cent; Blacks, 22.4 per cent). Population estimates for age and race were obtained from the US Census, and are specific for the five metropolitan counties served by the Atlanta cancer registry.[13]

Results

The overall breast cancer incidence rates increased with age. Rates of estrogen receptor negativity were higher than rates of estrogen receptor positivity in each five-year age group up to the ages of 50–54 years, where the curves crossed, a pattern generally consistent for Whites (Figure 1) and Blacks (Figure 2). However, the differential between curves for Black women was substantially wider than that for Whites, and Black women ages 30–44 years had higher incidence rates of estrogen receptor negative breast cancer than Whites.

Incidence rate ratios were calculated by age and receptor status (Table 2). Although most of the 95 per cent confidence intervals (CI) include unity, Whites generally have higher receptor positive cancer rates than Blacks among the age groups 35–54 years; Black women ages 30–44 had an excess of estrogen receptor negative cancer.

Logistic regression[14] was used to evaluate the potential confounding effects of stage of disease and laboratory variability on differences in receptor status between Whites and Blacks. The overall age-adjusted risk estimate for an estrogen receptor negative (as opposed to an estrogen receptor positive) tumor in Blacks compared to Whites was 1.9 (95 per cent

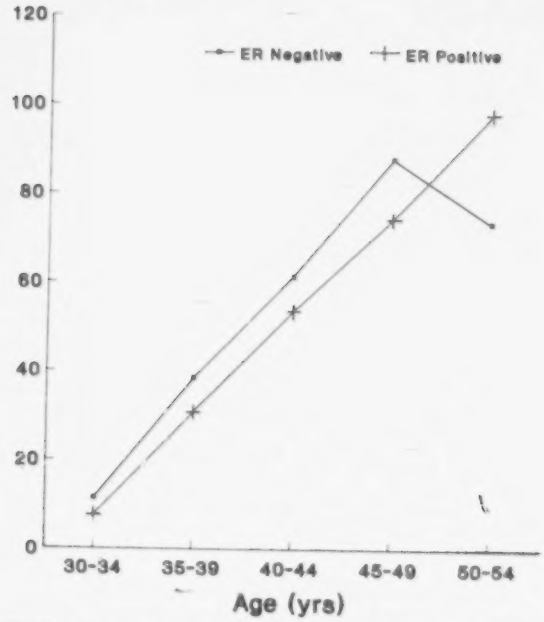

FIGURE 1—Average Annual Age-Specific Breast Cancer Incidence per 100,000 White Women

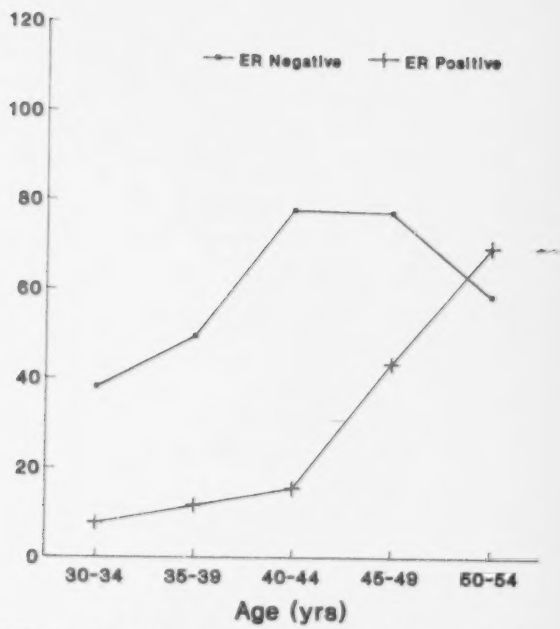

FIGURE 2—Average Annual Age-Specific Breast Cancer Incidence per 100,000 Black Women

CI = 1.2, 3.1) and did not change materially after adjustment for stage of disease at diagnosis or laboratory where the receptor assay was performed.

Discussion

The results of this study may have been influenced by a number of factors. Estrogen receptor results were unavailable for 17.6 per cent of the cases identified for study, but the age and race distributions of these cases did not differ substantially from those of cases included in the analysis. Exclusion of women with unknown receptor values resulted in slightly lower age-specific incidence rates for Whites and Blacks. If women with unknown receptor status had a distribution of estrogen receptor results similar to those with known status, the age-specific incidence patterns would be similar to those presented here.

Laboratory variability was not a factor. The majority of tumor specimens (for both Whites and Blacks) in this series of cases were analyzed at the same laboratory utilizing the same methodology. Furthermore, based on multivariate analyses, Blacks had a higher risk estimate than Whites for estrogen receptor negative (versus receptor positive) cancer, controlling for laboratory.

Multivariate analyses showed a higher risk estimate for estrogen receptor negative cancer (as opposed to estrogen receptor positive cancer) in Blacks compared to Whites after adjusting for age and clinical stage at diagnosis. Thus it does not appear that differences in extent of disease explain the observed differences in White:Black breast cancer rates by age and receptor status.

These age- and race-specific patterns of incidence rates for breast cancer are consistent with prior clinical and epidemiologic observations of an increase in the proportion of estrogen receptor positive cancer with advancing age,[4,5,10,12] and a lower prevalence of estrogen receptor positive breast cancer among Black women compared to White women.[5,8–10] The data suggest that younger women and Black women may be more likely to develop a more aggressive form of breast cancer, i.e., estrogen receptor negative disease.

Estrogen receptor negativity is associated with shorter disease-free intervals and survival in some cases.[1,2,15] In addition, Black women apparently have a lower proportion of receptor positive breast cancer compared to their White counterparts, in pre- and postmenopausal groups,[6,10,16] partly because they have more advanced disease at diagnosis and a higher proportion of poorly differentiated tumors.[6,16,17] The present analysis suggests that Blacks are at higher risk of estrogen receptor negative (as opposed to receptor positive) breast cancer than Whites, after adjustment for age and stage of disease at diagnosis.

Racial variation in estrogen receptor results has been

hypothesized as one explanation for the observed Black-White differences in breast cancer survival.[6,8,16,18] The present data provide further evidence that receptor negative breast cancer in Black women may be a contributing factor to their survival disadvantage. Future studies of Black-White differences in breast cancer survival should account for tumor estrogen receptor status.

ACKNOWLEDGMENTS

This study was conducted under an interagency agreement between the National Institute of Child Health and Human Development and the Centers for Disease Control, Atlanta, Georgia, with additional support from the National Cancer Institute, Bethesda, Maryland; and with contracts from CDC (200-80-0556) and NCI (N01-CN-61027 and N01-CN-55429) to the Georgia Center for Cancer Statistics.

Bowel Function and Breast Cancer in US Women

MARC S. MICOZZI, MD, PHD, CHRISTINE L. CARTER, PHD, MPH, DEMETRIUS ALBANES, MD, PHILIP R. TAYLOR, MD, SCD, AND LISA M. LICITRA, BA

Abstract: We studied bowel function in relation to 123 breast cancer cases among 7,702 women from the US NHANES I Epidemiologic Follow-up Study. Results suggest a slight increased risk of breast cancer for both decreased frequency of bowel movements (relative risk = 1.5, 95% confidence interval = 0.8, 2.7) and firm stool consistency (RR = 1.8, 95% CI = 1.0, 3.2.) These observations are consistent with an hypothesized association between constipation and increased risk of breast cancer. (*Am J Public Health* 1989; 79: 73–75.)

Introduction

There is indirect evidence that bowel function may be related to breast cancer risk. Petrakis and King found severe constipation (fewer than three bowel movements per week) to be associated with cytologic abnormalities in epithelial cells from breast fluid,[1] which are related to epithelial dysplasia in breast tissue.[2] Atypical proliferative breast disease is a significant risk factor for breast cancer in women; we, and others, have shown the risk to increase with increasing degree of epithelial atypia.[3,4]

Putative mutagens and carcinogens have also been detected in nipple aspirates of breast fluid.[5] Although the precise origin and mechanism of carcinogen delivery to the breast tissue are unknown, involvement of fecal mutagens, bowel function, and the enterohepatic circulation has been hypothesized. Intestinal bacteria produce carcinogens and mutagens, presumably through their actions on dietary constituents and/or bile acids.[6–8] Breast secretory (apocrine) epithelia selectively absorb and concentrate substances from the circulation originating from the gastrointestinal tract.[1,6,9]

Constipation, which results in greater contact time of stool in the intestine and hard stool consistency, may increase formation and absorption of fecal mutagens into the enterohepatic circulation and delivery to breast tissue.[10,11] We describe the first study relating aspects of bowel function directly to the risk of breast cancer in a cohort of women in the first National Health and Nutrition Examination Survey (NHANES I) Epidemiologic Follow-up Study.

Methods

NHANES I and its augmentation survey were conducted by the National Center for Health Statistics (NCHS) from 1971 to 1975.[12,13] These surveys provided cross-sectional information on medical history, anthropometric, biochemical, clinical, demographic, and nutritional factors in a large sample selected to represent the non-institutionalized popu-

[a]adjusted for current age, age at menarche, age at first birth, age at menopause, body mass index, socioeconomic status and family history

lation of the US. Children ages 1 to 5 years, women ages 20–44 years, the elderly (aged 65 years and over), and low-income individuals were oversampled. Details of a follow-up study of 14,407 adults (25 years or older) conducted between May 1982 and August 1984 were provided by Huntley, *et al.*[14] Of the original participants, 12,554 were successfully traced and reinterviewed (14 percent by proxy). Follow-up data included additional interview information, weight and blood pressure measurements, hospital and nursing home records, and death certificate information.

One hundred twenty-three (123) verified cases of breast cancer were identified in the NHANES I follow-up cohort. Women with self-reported breast cancer only (N = 36) were not considered as cases and conservatively included in the control group. There were 7,643 women in the cohort who did not develop breast cancer.

During the baseline interview, participants had been asked several questions about usual bowel habits: usual frequency (once per week or less, two to three times per week, four to six times per week, once per day, two to three times per day, or four or more times per day); characterization of frequent "bowel problems" (no trouble, frequent constipation or diarrhea, or both), and frequency of laxative use. Information regarding usual consistency of the stool (normal, loose, firm, or mixed) was asked only at follow-up.

Adjusted relative risks of breast cancer were calculated for bowel problems, bowel frequency, stool consistency, and laxative use using proportional hazards models from the SAS statistical procedure[15] PHLGM. Risk factors for breast cancer included in the multivariate models were current age as a continuous variable, age at menarche (<12, 12–13, ≥14), age at birth of the first child (<21, ≥22, nulliparous),* age at menopause, (≤45, >45, premenopausal), body mass index (<30.0, ≥30.0), socioeconomic status as poverty index ratio (<3.75, ≥3.75), and family history (one or more first-degree relatives with breast cancer; negative or positive). Reference categories for each of these variables are the first ones listed in each case. Missing data indicators were included in the Cox regression models in order to retain cases with data missing for specific variables only. Weight/stature[1.5] was employed as the body mass index in this study due to its high correlation with weight and independence from stature across age groups in this population sample.[17] Body mass index was chosen as a reliable index of body size that is of proven interest as a risk factor for breast cancer, and has strong significance for the complex inter-relations between nutrition, body size, and breast cancer.[10,18]

*Young age at first birth is highly correlated with increased parity, and the association of high parity with low risk of breast cancer has been explained by its association with young age at birth of the first child.[16]

Results

Laxative use was not a significant risk factor for breast cancer in the cohort (RR = 1.03, 95% CF = 0.91, 1.12) and it was not included in the final models. Table 1 reports relative risks of breast cancer for bowel problems, stool frequency, and stool consistency, adjusted for age and multiple risk factors. While a history of frequent diarrhea appeared to be associated with lower risk (RR = 0.5), the confidence interval was wide, based upon this number of cases. Self-reported constipation was not a predictor of adjusted breast cancer risk. However, the relative risk of breast cancer appeared to increase with decreased frequency of bowel movements. Firm consistency of stool was also associated with increased risk of breast cancer (RR = 1.8, 95% CI = 1.0, 3.2). Including multiple breast cancer risk factors (in addition to age) into the models somewhat increased the strength of the associations between breast cancer risk and both decreased stool frequency, and firm stool consistency. Excluding the 36 cases of non-verified breast cancer from the analysis, rather than including them in the control group, did not alter these results.

Discussion

Taken together these results suggest a slightly increased risk of breast cancer in women with less frequent and firm stools. Although these differences were not all "statistically significant" at $p < 0.05$, relative risks were at or above 1.5 with lower limits of the confidence intervals close to or including 1.0. These observations are consistent with a model of bowel function, breast and apocrine gland function, and breast cancer described by Petrakis, *et al*,[1,9] and recently critically reviewed.[10,11] However, our analyses were based upon self-reported bowel habits which could not be defined in totally objective terms. The self-reporting of "bowel problems" was not quantified in terms of stool frequency and consistency and is probably the least reliable measure,

perhaps accounting for the absence of risk associated with self-reported constipation.

Self-reporting of other bowel habits may also contribute to subjective misclassification of participants which would operate against the observation of any true relations between bowel function and breast cancer that may exist. Other limitations of these data include the fact that self-reporting of stool consistency was obtained at follow-up, rather than at baseline, and that other breast cancer risk factors not included in the model could have been confounders.

Further investigations into the relations between breast and apocrine gland function, bowel function and pre-neoplastic and neoplastic breast conditions are necessary to confirm the observed associations, and to elucidate the etiologic components of this model of breast carcinogenesis. Such investigations should focus on collection of dietary information and biologic samples (blood, breast fluid, stool), together with information on established breast cancer risk factors, in a defined population of women.

X-Ray Examinations during Pregnancy: National Natality Surveys, 1963 and 1980

RONALD G. KACZMAREK, MD, MPH, ROSCOE M. MOORE, JR., DVM, PHD, KENNETH G. KEPPEL, PHD, AND PAUL J. PLACEK, PHD

Abstract: Based on 1963 and 1980 National Natality Surveys, the rate of medical x-ray examinations during pregnancy per 100 mothers fell 34.2 percent. A decrease in chest x-ray examinations accounted for almost all of the decline in total x-ray examinations. The reductions were greater for older mothers and those who were not White. While the number of births fell from 4,071,000 in 1963 to 3,612,000 in 1980, the number of pelvimetry examinations actually increased by 45,000. (*Am J Public Health* 1989; 79:75–77.)

Introduction

The sensitivity of the fetus to ionizing radiation has been well documented.[1–4] The per rad increased risk of childhood leukemia has been estimated to be between 1.3 and 2.8 times the national incidence.[1–2] This increase is substantially larger than the increase expected from an equivalent dose administered to an adult population.[3]

Given the increased awareness during the 1960s and 1970s of the danger of fetal exposure to ionizing radiation, many observers predicted a decline in fetal dose from medical diagnostic procedures that utilize ionizing radiation.[5] Ultrasound became increasingly available during the 1970s, and was widely believed to have reduced fetal dose.[6] The precise health effects of fetal exposure to ultrasound are unknown, but some animal studies have suggested that the fetus may be adversely affected.[7]

We utilized data from the 1963 and 1980 National Natality Surveys (NNS) to obtain information about exposure to ionizing radiation among mothers who had live births.[8]

From the Center for Devices and Radiological Health (CDRH) of the Food and Drug Administration (Kaczmarek and Moore), and the National Center for Health Statistics (Keppel and Placek). Address reprint requests to Roscoe M. Moore, Jr., DVM, PhD, Chief, Epidemiology Branch, Division of Biometric Sciences (HFZ-116), Office of Science and Technology, CDRH, FDA, DHHS, 12200 Wilkins Avenue, Rockville, MD 20852. This paper, submitted to the Journal July 18, 1988, was revised and accepted for publication September 29, 1988.

Methods

The National Center for Health Statistics sampled 9,941 certificates of live birth in the 1980 NNS and 4,096 certificates of live birth in the 1963 NNS. Radiation information was sought from hospitals where mothers had delivered, from attendants at delivery, and from medical providers of radiation for all births. In both the 1963 and 1980 NNSs, detailed information regarding the mother's exposure to ionizing radiation during the 12 months prior to delivery was sought from the hospitals and from the attendants at delivery. The hospitals, attendants at delivery, and married mothers were all asked to identify any other sources that might have provided the mother with x-ray examinations prior to delivery. Health care providers identified in this way were also sent a questionnaire concerning the mother's radiation exposure.

Post-stratified ratio estimation procedures were used to produce national estimates of mothers exposed to radiation. These estimates of exposure may be understated to the extent that respondents failed to identify all health care providers that the mother saw during pregnancy, and to the extent that sources contacted failed to report all procedures performed. Although information was collected about radiation exposure during the 12 months before delivery, this analysis is limited to procedures performed during pregnancy. For relevant rates, 95 per cent confidence intervals were calculated.

In the 1963 NNS, response rates were as follows: married mothers—86 per cent; hospitals—98 per cent; and attendants at delivery—93 per cent.[9] In the 1980 NNS, response rates were as follows: married mothers—80 per cent; hospitals—76 per cent; and attendants at delivery—62 per cent.[6,7] The response rates for hospitals and attendants at delivery in the 1980 NNS understated the proportion of cases for which radiation exposure information is available since this information was collected not only from hospitals and attendants at delivery, but also from other providers as described above.

Results

The percentage of mothers who had one or more x-ray examinations during their pregnancies decreased in all age groups in 1980 (Table 1). Mothers 30–34 years of age experienced the largest decline (43.5 per cent), followed closely by mothers 35 years and over (41.6 per cent). All regions experienced a decline. The decline was greater for races other than White. Table 2 illustrates the trends in number and rate of x-ray examinations by broad classes of examinations. The total number of all x-ray examinations decreased by approximately 462,000, a 34.2 per cent decline in the rate per 100 mothers. The total number of chest x-ray exams decreased by approximately 452,000. However, the number of pelvimetries increased by 45,000, from 5.1 to 7.0 per 100 mothers.

Discussion

Other studies suggest a decline in x-ray examinations during pregnancy, but do not address whether a resultant decrease in fetal dose had occurred. Our analysis shows that almost all of the decrease in total examinations can be attributed to a decline in chest x-ray examinations. The 452,000 fewer chest x-ray exams performed in 1980 closely mirrors the drop of 462,000 total examinations noted between 1963 and 1980.

Studies during the 1970s questioned the value of routine prenatal chest x-rays and discouraged pelvimetry,[10–12] and so a drop in x-ray examinations during pregnancy was to be expected. For example, only a single benign lesion was uncovered by routine prenatal chest x-rays in a study of 1,200 patients.[10] Another study of 11,000 consecutive routine prenatal chest x-rays found no new useful information.[13]

On the other hand, the rate of pelvimetry per 100 mothers increased from 5.1 in 1963 to 7.0 in 1980, an increase of 37.0 per cent. The pronounced increase in the cesarean section rate that occurred between 1965 and 1980[14] may have contributed to the increase in the pelvimetry rate.

The absorbed fetal dose from a chest x-ray is relatively low.[15] The dose from a frontal projection chest x-ray has been estimated to be only approximately 20 millirad.[16] The lungs are relatively permeable to x-rays because air is less radiodense than soft tissue. Additionally, the fetus is not in the radiographic field during a chest x-ray and receives only scatter radiation. The estimated fetal dose from a posterior-anterior chest x-ray is in the range of 1 millirad.[13] Consequently, the degree of decreased fetal dose from the decline in chest x-ray examinations is relatively small.

In contrast to chest x-rays, the fetus is in the radiographic field during pelvimetry. This fact coupled with the greater radiodensity of the abdomen compared to the thorax results in an estimated fetal average dose of 620 millirad from a single pelvimetry,[5] far greater than the dose from a chest x-ray.

The decline from 1,117,000 to 655,000 in total examinations during pregnancy utilizing ionizing radiation has not translated into a commensurate decline in fetal dose. The large drop in chest x-rays has contributed little to decreasing fetal dose. Pelvimetry, which contributes much more to the fetal dose has actually risen in both absolute and relative terms between 1963 and 1980, according to the National Natality Survey (NNS).

The use of prenatal ultrasound is increasing[17] and has the

Records, Recall Loss, and Recall Bias in Pregnancy: A Comparison of Interview and Medical Records Data of Pregnant and Postnatal Women

HEATHER E. BRYANT, MD, PHD, NICOLA VISSER, MSC, AND EDGAR J. LOVE, MD, PHD

Abstract: To determine the agreement between interview-based and medical records data concerning illnesses and medications early in pregnancy, we compared the interviews of 202 women with the ongoing records collected during their pregnancies. Substantial underrecording of most transient illnesses was found. Fewer short-term illnesses were reported by postpartum women than still-pregnant women, suggesting the potential for recall bias or loss. (*Am J Public Health* 1989; 79:78–80.)

Introduction

Collection of data about the occurrence and timing of pregnancy events is fraught with potential problems in reliability. If a case and control group are compared, recall bias occurs if there is differential reporting by mothers of affected infants versus those of "healthy babies." Although a standard medical record, collected prospectively throughout pregnancy, may yield unbiased data, a recent comparison of medical records and women's reports of intrapartum events questioned whether the medical records are accurate.[1]

This paper compares self-reported data from still-pregnant and postpartum women with records data on potentially important events which occur during early pregnancy: medication use and history of transient illnesses.

Methods

The data presented derive from a sample of women from two control groups used in a larger study of risk factors for spontaneous abortion.[2] Three hospitals participated in the study between January 1984 and April 1985; these hospitals were the only three hospitals in a city of over 600,000 people which provided both emergency and routine obstetrical care. Overall response rate was 87.4 per cent for contacted prenatal women and 87.5 per cent for postnatal women in the larger study. In this report, the postnatal group consisted of women still in one of the three study hospitals following delivery of a normal infant. The prenatal group consisted of women less than 25 weeks pregnant, whose names were drawn from prenatal case lists provided by physicians admitting to one of the study hospitals, and matched by age (within five-year intervals) and parity (0, 1, 2+). "Late attenders" are thus not represented in this sample; 94.6 per cent of our entire group attended for care before the 16th week of gestation.

All women were interviewed regarding specific periconceptual exposures occurring up to four months following the last menstrual period. In addition to direct open-ended questions regarding exposure to short-term illnesses and medications, probes were used as "examples." For short-term illnesses, the probes included "colds, the flu, bladder infections, measles, mumps, other infections, etc.;" for medications the probes included "prescriptions, aspirin, cough medications, antinausea pills, cold medications, allergy preparations, vitamins, laxatives, etc."

At the end of the study, an abstractor who was unaware of the information on the original interview searched the hospital records of 101 pairs of prenatal and postnatal women. All hospital records contain a copy of the standard outpatient prenatal record form, which is filled out on an ongoing basis throughout the pregnancy by the attending physician and submitted to the hospital before delivery. This form contains information on past medical and drug history, and a record of each prenatal visit and problems discussed therein. Specific questions about vaginal bleeding and nausea appear on the form. For the women still pregnant at time of interview, prenatal forms were accessed after their delivery. However, only entries which covered the time up to and including the interview date were included in the analysis. Concordance was recorded only if interview and chart information agreed in the number and types of reports. Broad classifications of illnesses or drugs were used and exact concordance of proprietary names was not required.

We computed kappa values to compare the data abstracted from the prenatal hospital records with the interview data.[3] We also compared the 71 pregnant women who were interviewed after the sixteenth week of pregnancy, to their matched postnatal controls, calculating the differences in proportions and 95 per cent confidence intervals.[4] A matched analysis using binomial probabilities yielded similar findings and is not presented here.

Results

Health complaints were common during the first four months of pregnancy, but agreement between interview data and chart data was poor, with no kappa values exceeding 0.24 (Table 1). The major portion of agreement in all cases came from the absence of a complaint on either data source; positive concordance was much less common.

The interviews revealed a higher proportion of potentially infectious or febrile events than did the charts, but the charts reported more vaginal bleeding and nausea. For medication use, crude agreement was highest for prescription drugs.

When the interview histories of the first four months of pregnancy, as given by pregnant and postnatal women are compared, a pattern of more complete reporting of nausea/vomiting, upper respiratory infections, and flu/febrile illnesses by still-pregnant women is seen (Table 2). The pooled data of all short-term illnesses indicates more overall reports by still-pregnant women. For medication use, however, the difference between exposure reports by pregnant versus postnatal women is inconsequential in all categories.

TABLE 1—Agreement between Chart and Interview for Short-term Illness and Medication Reporting

	Source of Report						
	Interview Only	Chart Only	Both	Neither	Crude* Agreement	kappa¶	Interview: Chart Ratio†
Short-term Illness							
Upper respiratory infection/symptoms	45	2	3	152	76.7	.07	9.60
"Flu-like" or febrile illness	25	2	4	171	86.6	.19	4.83
Nausea/vomiting	8	34	5	155	79.2	.11	0.33
Vaginal spotting/ bleeding	2	26	3	171	86.1	.14	0.17
Other complaints	7	13	4	178	90.1	.24	0.65
Medication Type							
Prescription drugs	12	10	13	167	88.6	.48	1.09
Over-the-counter drugs	65	4	3	130	65.8	.02	9.71
Vitamins/supplements	88	11	82	21	51.0	.07	1.83

*Crude Agreement = [number of instances of reports on both records + number of instances of reports on neither record]/total number studied.
¶Kappa value is a measure of agreement beyond that which would be expected to occur by chance. A maximum value for kappa is 1.0; levels below 0.4 are generally taken to indicate poor agreement.
†Interview: Chart Ratio = number of instances of positive reports on interview/number of instances of positive reports on chart.

Discussion

It has been noted that a high proportion of women interviewed one to 15 months postpartum fail to give drug and intermittent illness history identical to that recorded in an interview at five months' gestation.[5] Agreement between birth certificates and mother's reports of time of onset of prenatal care is concordant for month in only 44 per cent of cases,* and concordant for trimester of onset in 88 per cent for White subjects,[7] with mothers tending to report earlier care than the certificates. Distant recall of drug use in past pregnancies has been found to be poor even for prescription drugs.[7] Some have suggested that, because this recall error (i.e., loss) can create inaccurate results in retrospective studies, "studies of past discontinued drug use must, in most instances, rely on prerecorded, reasonably complete documentation of use."[8]

This study used prospective ongoing records, and yet revealed systematic and substantial underrecording of infectious or flu-like illnesses, and of vitamins and over-the-counter drugs. Possible explanations for these failures to record information include:

- The woman may judge that such events as short-term febrile illnesses or use of over-the-counter drugs are too insignificant to report to a physician. This also implies that physicians do not specifically ask for this information.
- Physicians may feel that only those items known to be detrimental to pregnancy should be regularly recorded. More closed-ended questions (such as those on nausea and vaginal bleeding in this study), supplemented by open-ended ones, might improve recording practices.

Women who were still pregnant at the time of the

Medication type						
Prescription drugs	13	18.3	10	14.1	4.3	(−7.9, 16.3)
Over-the-counter drugs	31	43.7	22	31.0	12.7	(−3.1, 28.4)
Vitamins/supplements	60	84.5	58	81.6	3.1	(−9.5, 15.1)
Total reports cited*	104	48.8	90	31.0	6.5	(−2.9, 16.0)

*Represents total of illness classifications cited. Total denominator for short-term illness is 355 (5 complaints categories for 71 women); for medications is 213.

interview reported short-term illnesses, but not medication use, more frequently. This could reflect bias if symptomatic women were more likely to appear for prenatal care before the sixteenth week of pregnancy. However, because 94.6 per cent of our total postnatal study sample had appeared for care before 16 weeks' gestation, such a bias is unlikely. It is more likely that the postnatal women had either forgotten these events or dismissed them once a normal delivery had occurred. Either explanation argues for a potential recall bias to occur if such postnatal controls were used to compare data on early pregnancy exposures with mothers of malformed or seriously ill infants, who may be less inclined to underreport any potentially related event.[9]

Government Report Assesses Quality of Medical Care

The Office of Technology Assessment has released an in-depth report on the quality of medical care in the US. *The Quality of Medical Care: Information for Consumers* evaluates the reliability, validity, and feasibility of specific social indicators which affect the quality of medical care that purchasers—individuals, employers, and third party payers—might use. The report assesses eight potential indicators of the quality of care:

- hospital mortality rates, for the institution, overall by department, and by condition or procedure;
- adverse events that affect patients, as exemplified by hospital-acquired infections;
- formal disciplinary actions against physicians by State medical boards sanctions imposed by the US Department of Health and Human Services (HHS) on the recommendations of utilization and quality control peer review organizations (PROs), and malpractice compensation;
- evaluation of physicians' performance through their care for a particular condition, as exemplified by hypertension screening and management;
- volume of service in hospitals or performed by physicians;
- scope of hospital services, with particular reference to emergency services, cancer care, and newborn intensive care units;
- physician specialization; and
- patients' assessments of their care.

This 330-page publication, *The Quality of Medical Care: Information for Consumers*, stock number 052-003-01114-0, is available for $14. Send prepayment to Dept. 36-BX, Superintendent of Documents, Washington, DC 20402-9325; or to order with VISA or MasterCard phone (202) 783-3238.

HIV Seroprevalence in Intravenous Drug Users: Los Angeles, California, 1986

LAURENE MASCOLA, MD, MPH, LOREN LIEB, MPH, KENNETH A. IWAKOSHI, MS, DON MCALLISTER, MA
TED SIMINOWSKI, PHD, MARJORIE GILES, BA, MA, GRACE RUN, MS,
SHIRLEY L. FANNIN, MD, AND IRMA H. STRANTZ, DRPH

Abstract: To estimate the seroprevalence and investigate risk behaviors for HIV (human immunodeficiency virus) infection in intravenous drug users in Los Angeles County, a stratified, random sample of 790 clients, enrolled in either methadone maintenance or detoxification programs, were studied. Thirteen study participants (1.8 per cent) were seropositive; of these, five were homosexual/bisexual males and three were female prostitutes. Ninety-five per cent of all participants reported sharing needles. Risk reduction education efforts must be expanded before the HIV antibody prevalence rate increases. (*Am J Public Health* 1989; 79:81–82.)

Introduction

As of December 1987, 11 per cent of the 4,243 reported acquired immunodeficiency syndrome (AIDS) cases in Los Angeles County (LAC) had a history of intravenous drug use. Intravenous drug use was the sole risk behavior for 3 per cent of the cases, in contrast to the distribution of cases on the East Coast where as many as 50 per cent of AIDS patients have reported intravenous drug use as the primary risk factor.*

An estimated 120,000 active heroin addicts reside in LAC.** In 1984–85, 25,396 clients were admitted to drug treatment programs in LAC for primary parenteral substance abuse; 98 per cent were heroin users. To obtain an estimate of the prevalence of the human immunodeficiency virus (HIV) infection in intravenous drug users (IVDUs) in LAC, a serologic survey in methadone treatment programs was conducted.

Methods

Between April and July 1986, 790 study participants were selected from the approximately 25,000 IVDUs who annually receive treatment at 31 licensed outpatient methadone maintenance and detoxification centers in LAC. The sample was stratified according to clinic location and drug treatment program type (methadone maintenance or detoxification) in an attempt to obtain a representative sample of IVDUs with respect to age, race, sex, and socioeconomic status. Participants were randomly selected within stratification categories. After obtaining informed consent, participants were interviewed and a blood sample was obtained. Age, race, sex, and treatment modality were obtained for all those who refused participation. Clients who had not used drugs intravenously since 1978 were excluded.

Blood samples of participants were analyzed for the presence of antibody to HIV. Samples which were repeatedly reactive using an enzyme-linked immunosorbent assay (ELISA) were confirmed by indirect fluorescence assay (IFA) and Western blot analysis.

Data analysis was performed using Fisher's exact test, chi-square test, RxC Fisher's exact test, t-tests and exact odds ratios and confidence intervals.[1–3]

Results

Ninety-two per cent of the 790 persons offered HIV testing agreed to participate. Nonparticipants differed from the participants with respect to their drug program status; nonparticipants were more likely to be in detoxification programs than participants. Thirteen participants (1.8 per cent) had antibody to HIV as detected by ELISA, IFA, and Western blot analysis. Of the seropositives, three were female prostitutes, five were homosexual/bisexual males, one participant's spouse had died of AIDS, and one had frequented shooting galleries in New York City. The seropositive and seronegative participants did not differ with respect to age, sex, race, education, or drug treatment modality. Forty-six per cent of the seropositives had salaries greater than $20,000 per year versus 16 per cent in the seronegative group (OR = 4.45, CI = 1.21, 15.79).

Compared to heterosexual males, homosexual and bisexual males were 65-fold (CI = 3.73, 997.58) and 13-fold (CI = 1.45, 162.10), respectively, more likely to be seropositive. Twelve per cent of homosexual/bisexual males were seropositive. No seropositive males reported contact with female prostitutes. A greater proportion of seropositive females (50 per cent) were prostitutes than seronegative females (19 per cent). Four per cent of female participants who admitted to prostitution were seropositive.

The seronegative and seropositive participants began using drugs at a mean age of 21 and 20 years, respectively. Both groups injected frequently and used many types of drugs (Table 1). Approximately three-fourths of the seronegatives and two-thirds of the seropositives injected drugs at least once a day. Seropositives were more likely to speedball (inject both cocaine and heroin together) than seronegatives (OR = 2.9, CI = .82, 11.39, Fisher's p-value = .01) and to boot drugs (withdraw blood into syringe before injecting) (OR = 3.3, CI = .94, 12.93, Fisher's p-value = .03).

The majority of participants shared needles one or more times per week (Table 1). Information obtained on 37 participants who shared needles showed that two-thirds (24) shared only with a spouse, relative, or steady friend. An almost equal proportion of seropositive and seronegative participants (39 per cent and 31 per cent, respectively) injected drugs in shooting galleries. Over 63 per cent of the seronegatives and 85 per cent of the seropositives had been incarcerated at least once.

Discussion

The HIV seroprevalence rate of 1.8 per cent among IVDUs was surprisingly low for this large metropolitan area. Our data are consistent with studies among other IVDUs in treatment programs throughout California. Results from these studies have demonstrated seroprevalence rates ranging from 1.7 to 10 per cent.[4–6]

The epidemiologic characteristics of local AIDS cases are consistent with the low seropositivity rate observed in this study. Of the 2,026 AIDS cases reported at the time of this study, only 46 cases (2 per cent) had intravenous drug use as their only risk behavior with an additional 9 per cent of cases reported among homosexual/bisexual IVDUs. One year later in July 1987, the percentage of AIDS cases with intravenous drug use as their only risk behavior had only risen to 3 per cent. Six pediatric AIDS cases, perinatally exposed to HIV, were associated with IVDUs. The low number of cases associated with IVDUs provides additional indirect support for the low seroprevalence rate found.

Consistent with other studies, our data indicate that seropositive users are more likely to speedball and boot drugs.*** The association with booting perhaps can be explained by an increased chance of blood-virus contact in the syringe.

Our seroprevalence estimate of 1.8 per cent is a conservative one as our sample did not contain "street addicts," a group at higher risk for HIV infection. Our data may also not accurately reflect the HIV seroprevalence among minority IVDUs, especially among the Black population. Our sample also included a higher proportion of females (48 per cent) than the general population of IVDUs in treatment (35 per cent).**

The seroprevalence among IVDUs in LAC may be low because LAC does not have the large, anonymous shooting galleries that are present on the East Coast.

Our own limited data, and a recent HIV seroprevalence survey among IVDUs in Los Angeles County, showed that the vast majority (74 per cent) of users shared drugs with known acquaintances such as friends, family members, or sex partners.** Therefore, infection may be contained within these smaller groups preventing the spread of HIV to a larger population of IVDUs. LAC's large geographic metropolitan area may also isolate groups of IVDUs thereby inhibiting the spread of infection.

Although the prevalence of HIV infection in IVDUs in LAC is low, needle sharing and other high-risk behaviors in this population will likely cause this prevalence to increase in the next few years unless effective interventions are implemented.

An Outbreak of Syphilis on an Indian Reservation: Descriptive Epidemiology and Disease-Control Measures

A. Russell Gerber, MD, Leland C. King, Gerald J. Dunleavy, and Lloyd F. Novick, MD, MPH

Abstract: From January 1983 through January 1985, 88 cases of early adult syphilis and five cases of congenital syphilis were identified among residents of a southwestern Indian reservation. The male-to-female ratio of primary and secondary syphilis cases was 1.7: 1; over 90 per cent of women were of childbearing age. Using community health workers to determine the social circles of infected persons was effective in identifying persons at risk; treatment of partners of infected persons prior to development of seroreactivity contributed to the successful control of this outbreak. (*Am J Public Health* 1989; 79:83–85.)

Introduction

This report summarizes a large syphilis outbreak among residents of a southwestern Indian reservation. Conventional outbreak-control measures failed to prevent continued transmission. Identification of sexual partners by a variation of cluster techniques was vital in the control of this outbreak.

Background

Before 1983, the total number of cases for all stages of syphilis reported in any one year from this Indian reservation had never exceeded four. In 1983 and 1984, 88 cases of primary, secondary, and early latent syphilis among residents of the Indian reservation were reported to the Arizona Department of Health Services (ADHS), an increase in incidence of primary and secondary (P & S) syphilis from 32.7 cases per 100,000 population in 1982 to 163.8/100,000 in 1983 and 458.7/100,000 in 1984 (1980 estimate of the reservation population was 6,104, US Bureau of the Census). In addition, five cases of early congenital syphilis (CS) were reported.

Conventional outbreak-control measures between September 1983 and November 1984 consisted of case-finding and treatment of sexual partners identified by interview of infected persons. The report of three CS cases among reservation residents in November 1984 signaled failure to control the outbreak. This prompted an intense investigation, reevaluation of traditional control strategies, and adoption of a novel approach to secondary disease prevention using "cluster" interviewing techniques.

Clinical health care on the reservation is provided by the Indian Health Service (IHS) which maintains a hospital and a small clinic. Occasionally, reservation residents will seek primary care at off-reservation hospitals in nearby cities. Tertiary care is provided at referral hospitals in Phoenix.

Address reprint request to Dr. A. Russell Gerber, Division of Infectious Diseases and Immunology, Department of Pediatrics, Emory University School of Medicine, 69 Butler St, SE, Atlanta, GA 30303. Mr. King is now with the North Carolina Department of Human Resources, Raleigh; Dr. Novick is now with the Center for Community Health, New York State Department of Health, Albany. This paper, submitted to the Journal November 27, 1987, was revised and accepted for publication June 13, 1988.

Methods

The study period was January 1, 1983 to January 31, 1985. A diagnosis of P & S syphilis was made in persons with a positive serologic test for syphilis who had characteristic genital lesions or generalized rashes with palmar and plantar predilection. Early latency was diagnosed in persons without lesions who had positive serologic tests for syphilis and who had within the previous one year a nonreactive serological test, or symptoms highly suggestive of P & S syphilis, or exposure to sex partners with definitive or presumptive P & S or early latent syphilis, or a less than fourfold increase in titer on serial nontreponemal tests.[1] Suspects were defined as persons cited by patients during interview not as sex partners but as persons who might "profit from serologic testing".[2]

Difficulties in determining sexual partners through patient interview prompted screening of persons identified as high-risk through a variation of the cluster intervention technique. Community health workers were routinely interviewed regarding each case. "Close associates" were defined as persons seen frequently with infected persons by community health care workers and not named on patients' interview. All sexual partners, suspects, and close associates were informed of the availability of serologic testing for syphilis and were urged to accept treatment.

A probable case of early CS was defined as a live-born infant: 1) born to a mother with high risk for transmitting syphilis to her newborn (untreated early syphilis at the time of delivery); 2) with a positive serologic test for syphilis; plus 3) major clinical findings consistent with congenital infection.[3] A possible case of early CS was defined as above, but without the major clinical findings.

Control efforts during the outbreak included special sexually transmitted disease (STD) clinics and community outreach programs in which a total of 1,172 of the 6,104 residents of the reservation were serologically tested for syphilis, as were 80 tribal members who lived off the reservation.

Nine hundred sixty-seven persons either volunteered or were referred to the STD clinic and were serologically tested for syphilis. To increase community awareness and outreach, educational programs and serologic testing were also offered in nearby off-reservation bars, alcoholic rehabilitation centers, workplaces, and community meetings. An additional 285 native Americans were tested at these alternate locations on and off the reservation.

Results

Epidemiological Investigation

Increases in cases of P & S syphilis were first recognized during August–September 1983 when six cases were reported to ADHS (Figure 1). The majority of P & S syphilis cases occurred before May 1984. A rapid rise in syphilis cases occurred in October–December 1984. The first early CS case occurred in December 1983. Four of the five infants with early CS were born between August and December 1984. On record review, all five CS cases had deficiencies in prenatal care. Three had serologic tests for syphilis performed at the

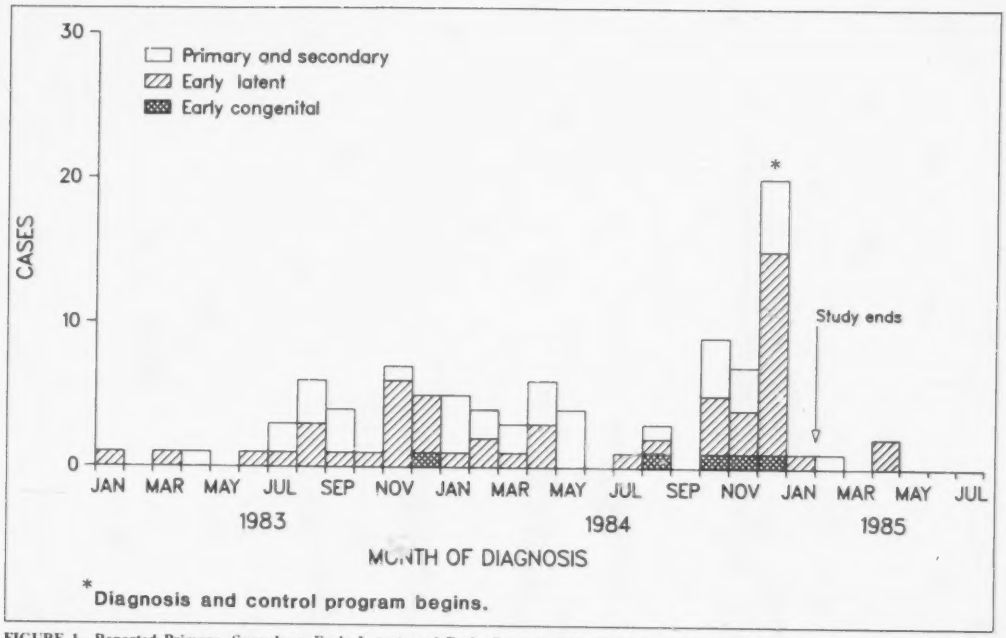

FIGURE 1—Reported Primary, Secondary, Early Latent, and Early Congenital Syphilis Cases, by Month of Diagnosis, Southwestern Indian Reservation, January 1983–July 1985

first prenatal visit, but not again during the third trimester; one did not receive prenatal care; and one with a reactive serologic test for syphilis was lost to follow-up until delivery. All infants received adequate treatment.

Of the 93 reported cases of syphilis, 38 (40.9 per cent) were P & S syphilis, 50 (53.8 per cent) were early latent syphilis, and 5 (5.4 per cent) were early CS. Of the five infants with early CS, three were classified as probable CS cases and two as possible CS cases.

Males accounted for 24 (63.2 per cent) of the persons with P & S syphilis, a male to female ratio of 1.7:1. Ages of P & S syphilis patients ranged from 14 to 48 years, with a median age of 25.5 years (males, 26.0; females, 24.0). Over 90 per cent of the females with P & S syphilis were of childbearing age (15–44 years old). The age and sex characteristics of the patients with early latent syphilis were similar to the patients with P & S syphilis.

Results of Serologic Screening

As a result of the serologic screening, a total of 24 cases were identified and treated. Three cases were identified in members of other Indian tribes living on other reservations but who had been identified as associates of residents on the index reservation; 21 cases were identified in reservation residents (Table 1). No new cases were identified in the 80 tribal members tested who lived off the reservation.

Twelve of the 20 new cases diagnosed in the STD clinic were detected among "close associates" of known cases (relative risk = 8.3; 95 per cent confidence interval: 2.9, 23.5) (Table 1). Only screening of persons actually named as partners identified new syphilis cases at a higher rate than screening "close associates."

Discussion

While the incidence rate of syphilis on American Indian

*Risk of identifying a new case of syphilis relative to the rate per 100 examined or tested in a low-risk population (volunteers: 0.5/100).

reservations has decreased over the last 50 years,[4] it still remains higher than the rate for the general United States population. Preventive efforts on Indian reservations have seldom departed from the model developed for other areas—contact tracing through interview and follow-up—which relies on a case-patient naming all sexual contacts. Prompt location of persons identified by laboratory screening or interview is vital to the effectiveness of this strategy.

The control of this outbreak depended to a large degree on the utilization of knowledge possessed by community health workers to identify persons at potential risk of contracting syphilis when traditional strategies failed to prevent transmission. Close associates identified by community health workers through cluster interviewing had substantially higher rates of newly diagnosed syphilis when serologic testing was performed.

Arizona state law requires pregnant women to have prenatal serologic testing for syphilis. If prenatal care had been received and serologic tests for syphilis had been performed both at the first prenatal visit and again during the third trimester, as recommended,[3] all of the early CS cases could have been prevented.

ACKNOWLEDGMENTS

The authors gratefully acknowledge the cooperation of the Indian Health Service physicians and administration as well as the Indian Tribe. We thank Sandra Yellowhawk, Phillip Talboy, and Steve Hurwitz for their work with patients. We also thank Drs. E. Russell Alexander, Steven J. Englender, and Glyn G. Caldwell for reviewing the manuscript. Debra L. Rush-Gerber and Alyce Michas provided technical assistance.

10,000 Homes to be Tested in Yale Radon Study

A five-year research project to help resolve some of the scientific issues relating to the radioactive gas radon and cancer will be conducted by a team of Yale University School of Medicine researchers. Funded by the National Institute of Environmental Health Sciences, located in Research Triangle Park, NC, the $3.9 million project at Yale is one of only two in the US; the other one is at the University of Utah.

This study will "carefully evaluate the serious health effects at the low end of the radon exposure scale, evaluate the interaction of radon and cigarette smoke, and consider the issue of radon as a potential risk-factor for childhood cancers," according to Stuart L. Shalat, ScD, assistant professor of medicine and epidemiology, who heads the study.

Dr. Shalat has long been interested in the effects of radiation and other issues related to occupational/environmental health. He worked in the New York State Health Department investigating illness associated with the Love Canal toxic waste site between 1978 and 1981.

Using an alpha-track monitor, the Yale researcher will measure radon levels in 10,000 houses throughout Connecticut. The device uses a film-like photo emulsion to count the number of tracks. By knowing how long the device has been measuring the presence of radon in homes, one can accurately determine the radon level. Residing in approximately one-fourth of the homes to be tested are adults with newly diagnosed cases of lung cancer, or children with new cancers. The rest of the test homes, with healthy residents, will be randomly selected. Team members will interview residents who agree to participate and will monitor their homes for a year between 1989 and 1992.

In October, the US Environmental Protection Agency identified radon, a colorless, odorless, tasteless gas, as a serious environmental health concern, and stated that radon contamination needs to be reduced in homes with levels higher than four picocuries per liter of air. A picocurie is one trillionth of a curie, a standard measure of radiation.

Radon has been a public health issue for the past five years, as more and more people have expressed concern about indoor air pollution. Because of energy-conservation measures, more people have been sealing their homes more tightly, which may increase the levels of radon and other indoor-air contaminants.

Faculty members in the departments of epidemiology and public health and internal medicine will collaborate on the study, in conjunction with the Connecticut State Tumor Registry and the Yale Comprehensive Cancer Center.

NEW MASTER'S AND DOCTORAL DEGREE PROGRAMS IN HEALTH PROMOTION AND HEALTH EDUCATION LAUNCHED AT THE UNIVERSITY OF TEXAS SCHOOL OF PUBLIC HEALTH

Applications for admission in Fall 1989 to master's and doctoral programs in health promotion and health education are now being accepted.

The program of study integrates behavioral and social science theory and intervention at the individual, organizational, and community levels; program planning and evaluation; survey research and other assessment methods; health economics; and health policy. Major resources for students include the Center for Health Promotion Research and Development, the Southwest Center for Prevention Research, the Center for Prevention of Injury and Violence, the Texas Medical Center, and behavioral science programs at Rice University and the University of Houston.

For further information, write to Dr. Patricia D. Mullen, Associate Professor and Convener, Health Promotion/Health Education Module, P.O. Box 20186, School of Public Health, University of Texas Health Science Center, Houston TX 77225.

The Smoke-Free Guide:
How to Eliminate Tobacco Smoke from Your Environment by Arlene Galloway, MHSc.

This book by a public health professional offers positive approaches to create smoke-free homes, work places and public places. It includes information on the health consequences of tobacco use and exposure to environmental tobacco smoke, and suggests methods useful to those who want to quit smoking. It also provides information on international health efforts on the tobacco issue.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health*, 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

Advertising Sales: Mary Beth Kammann, Advertising Manager, APHA, 1015 15th St., NW, Washington, DC 20005. Tel: (202) 789-5668 or 5600. All advertising is accepted with the understanding that products and services are professionally related and meet the ethical standards of public health practice. Acceptance by the Journal does not indicate or imply endorsement by the Journal or APHA.

Reprints: Request single reprints of articles published in the Journal from the authors at the address given in the footnote on first page of published article. Effects of the Antismoking Campaign: An Update

KENNETH E. WARNER, PhD

Abstract: In the absence of the antismoking campaign, adult per capita cigarette consumption in 1987 would have been an estimated 79–89 per cent higher than the level actually experienced. The smoking prevalence of all birth cohorts of men and women born during this century is well below that which would have been expected in the absence of the campaign. As a consequence, in 1985 an estimated 56 million Americans were smokers; without the campaign, an estimated 91 million would have been smokers. As a result of campaign-induced decisions not to smoke, between 1964 and 1985 an estimated 789,200 Americans avoided or postponed smoking-related deaths and gained an average of 21 additional years of life expectancy each; collectively this represents more than 16 million person-years of additional life. The greatest health benefit lies in the future, however, as younger individuals reach the ages at which smoking claims its greatest toll, and as middle-aged former smokers realize relative reductions in smoking mortality risks as a result of long-term abstinence from smoking. For example, campaign-induced decisions not to smoke made prior to 1986 will result in the postponement or avoidance of an estimated 2.1 million smoking-related deaths between 1986 and the year 2000. (*Am J Public Health* 1989; 79:144–151.)

Introduction

Previous papers have presented estimates of the effect of the antismoking campaign between 1964 and 1978 on two measures of smoking behavior[1,2] and on smoking-related mortality.[3] The present paper updates the findings of the earlier studies.

Throughout this paper, the term "antismoking campaign" is used not to connote a specific set of activities oriented toward smoking prevention and cessation, but rather the collectivity of all such activities and the changing social norms that have accompanied them. In essence, "antismoking campaign" serves as a short-hand expression covering the entirety of changes in the social environment spawned by scientific and social interest in the hazards of smoking. A detailed discussion of those changes—in scientific and public knowledge, smoking attitudes and behaviors, and programs and policies—is found in the Surgeon General's 1989 report on smoking and health.[4]

Methods

Adult per Capita Consumption

An objective measure of the nation's cigarette smoking behavior, used in numerous empirical studies, is adult per capita cigarette consumption, defined as total cigarette consumption (from the Economic Research Service of the US Department of Agriculture) divided by the population over 17 years of age; its advantages and disadvantages have been discussed elsewhere.[5] To assess the impact of the antismoking campaign on cigarette consumption, as in the previous analysis[1] (and a predecessor study[5]), I employ ordinary least squares regression analysis on per capita consumption as the dependent variable. Independent variables include those conventionally found in demand analyses, such as price, and a series of variables representing major antismoking "events," such as publication of the Surgeon General's first Report on Smoking and Health[6] and the growth of the nonsmokers' rights movement. Time series data for the study cover the period 1947 through 1987. Estimated regression coefficients for the antismoking variables indicate the specific association between each "event" and per capita consumption.

From the regression results, one can also estimate the aggregate impact of the antismoking campaign in any given year by adding the values of all of the relevant antismoking variables, multiplied by their regression coefficients, to the year's actual per capita consumption. (Since the previous year's consumption is included in the regression as an independent variable, as a measure of the addiction effect, an antismoking effect is also carried forward into future years through this variable.) The resulting estimates of per capita consumption in the absence of the campaign are then compared to the actual levels of consumption to estimate the aggregate impact of the campaign in the year in question. Details on the specifics of the methodology are found in the previous analysis.[1]

Smoking Prevalence in Age- and Sex-Specific Cohorts

The second study of smoking behavior relies on *prevalence*—the most common index of the national level of smoking. In this assessment of the impact of the campaign, age- and sex-specific estimates of actual smoking prevalence derived from self-reported survey data (and therefore labeled "reported" prevalence) are compared with estimates of prevalence rates that would have been expected in the absence of the antismoking campaign (herein referred to as "expected" prevalence).

As in the earlier study,[2] the population born between 1901 and 1960 is divided into 12 age-sex cohorts, each incorporating 10 birth years. Cohort-specific smoking rates for the years 1964–78 are taken directly from the previous study, which employed retrospective self-report data* derived from the 1978 National Health Interview Survey (NHIS). For the years 1979-85, cohort-specific prevalence data are derived from the 1979, 1980, 1983, and 1985 NHIS.** For the years in which survey data are not available (1981, 1982, and 1984), linear interpolations from the available surveys are used.

To develop estimates of what the various cohorts' smoking rates would have been from 1964 through 1985, in

the absence of the antismoking campaign ("expected" prevalence), the analysis adopts the assumption that well-established smoking patterns or trends prior to 1964 would have persisted into the future. For men, this would mean approximate continuation of the smoking frequencies of earlier cohorts, whereas for women it would mean continuation of the growth in smoking experienced primarily since World War II.

The basic formula for developing these estimates involves adding or subtracting earlier cohorts' average percentage point changes in smoking prevalence, at comparable ages, to the 1963 base rate prevalence of the cohort in question. For example, during 1964 the 1941–50 male cohort consisted of males 14 to 23 years of age. To calculate their expected smoking prevalence in 1964, in the absence of the antismoking campaign, I add to their 1963 prevalence the average of the percentage point changes in the smoking rates of the 1931–40, 1921–30, and 1911–20 male cohorts in the years in which these cohorts were 14 to 23 years old (1954, 1944, and 1934, respectively). To calculate the 1965 expected smoking prevalence for the 1941–50 cohort, I add to the 1964 estimate the average percentage point change of the three comparison cohorts in 1955, 1945, and 1935. The same procedure is repeated for 1966 and ensuing years.

This basic procedure was applied directly to the four youngest male cohorts. For the two eldest male cohorts and all of the female cohorts, variations on the basic procedure or cohort-specific ad hoc procedures had to be applied. These are described in Appendix A.

Reported and expected prevalence rates are converted into estimates of the numbers of smokers, with and without the antismoking campaign, by multiplying cohort-specific prevalence rates by the cohort's population in a given year. For the expected number of smokers in the absence of the campaign, cohort populations are adjusted downward to reflect the differential mortality rates of smokers and nonsmokers. (The needed adjustments are developed in the "deaths postponed" analysis described below.)

Deaths Postponed by Campaign-Induced Decreases in Prevalence

The third analysis estimates the number of smoking-related deaths postponed or avoided as a consequence of campaign-induced decisions to quit smoking or not to start. In the earlier analysis, this health benefit was labeled "premature deaths avoided."[3] In the present updating, the terminology is changed to "deaths postponed" to clarify that the health benefit includes both complete avoidance and mere postponement of smoking-related deaths. Interest is in the loss of life expectancy of smokers compared to nonsmokers, whether smoking-related deaths occur at age 50 or age 70.

As in the previous analysis,[3] the number of deaths postponed is estimated by applying epidemiologic data on age- and sex-specific mortality rates of smokers, quitters, and never smokers to the cohort-specific changes in smoking prevalence discussed in the preceding section. The reduced mortality rates of quitters (compared with continuing smokers) are multiplied by the estimated number of campaign-induced quitters and non-initiators (i.e., people influenced by the campaign not to start smoking) in each cohort and in each year from 1964 through 1985. This procedure generates estimates of the number of additional smoking-related deaths that would have occurred during those years had the antismoking campaign not encouraged quitting and noninitiation. To estimate the number of life-years saved associated with each death postponed, life expectancy gained is calculated by comparing the former smoker's life expectancy with that of a continuing smoker, using life table analysis.

Much of the postponement of death due to smoking cessation and noninitiation induced by the campaign through 1985 will not be realized until later years. For example, someone who quits smoking in 1985, who would not have experienced a smoking-related death that year, might avoid a smoking-related death that would have occurred 15 years later (e.g., by avoiding the development of lung cancer). By "aging" the population of quitters and noninitiators alive in 1985 and applying to them the differential mortality rates of former smokers, one can estimate the numbers of smoking-related deaths postponed or avoided in the future as a result of quitting and noninitiation that occurred prior to the end of 1985.

Given the need to make several assumptions to develop estimates of deaths postponed, the base-case findings are subjected to four sensitivity analyses. Assumed values of each of four variables are altered in a conservative direction to determine whether the specific values selected for the base case fundamentally affect the qualitative findings of the study. The four sensitivity analyses include:

- running the estimating model with all excess smoker mortality ratios reduced by 50 per cent;
- increasing ex-smoker mortality ratios by 25 per cent,
- reducing estimates of the number of campaign-induced quitters and noninitiators by 25 per cent, and
- allowing for 50 per cent recidivism among one-year and two-year quitters and noninitiators. ("Recidivism" by a noninitiator means that someone influenced by the campaign not to start smoking in a given year decides to start smoking a year or two later.)

The precise estimating procedures for the analysis of deaths postponed from 1964 through 1985 are methodologically identical to those described in an appendix to the original study,[3] subject to one refinement. When five-year population age groupings have to be broken up to provide estimates of the population at specific ages in specific years, Karup-King coefficient formulas[7] are used; the previous analysis relied on simple averaging. Data are identical for both studies for the period through 1978. For the post-1978 period, the new age-sex cohort differences between actual and expected smoking prevalence, described in the preceding section, are used in the mortality analysis, as are more recent life table data. Other parameter values are unchanged from the original analysis.

Results

Adult per Capita Consumption

The regression model detailed in Appendix B indicates which factors reduced per capita consumption. Findings with respect to the significance of individual variables are qualitatively identical (and quantitatively very close) to those reported in the earlier study.[1] For the antismoking "events," this means that significant decreases in per capita consumption ranging from 3.5 to 7.5 per cent occurred during each year of prominent adverse smoking-and-health publicity represented by dummy variables in the regression. These include the first public smoking-and-cancer "scare" of 1953–54, publication of the Surgeon General's first Report on Smoking and Health in 1964,[6] and the three full years of the Fairness Doctrine period, 1968–70, during which broadcasters were required by the Federal Communications Commission to donate air time to the antismoking message to

"balance" pro-smoking advertising.[8] The regression also shows a strong inverse correlation between per capita consumption and growth in the number of states having laws restricting smoking in public places. Finally, the regression indicates a price elasticity of demand for cigarettes of −0.2. This means that a cigarette price increase of 10 per cent is associated with a per capita consumption decrease of 2 per cent.

The aggregate impact of the campaign on per capita consumption is shown in Figure 1, which depicts both actual adult per capita consumption and two patterns of consumption estimated in the absence of the campaign. The dashed line represents an estimate in which price changes are independent of the campaign, while the dotted line reflects the assumption that the pattern of price changes, affected most strongly by state excise taxation of cigarettes, was itself a function of legislators' reactions to the emerging evidence on smoking and health. The logic underlying the latter assumption is that, influenced by numerous state tax increases, the real price of cigarettes rose eight consecutive years following publication of the Surgeon General's first report.[1,9] A period of new-tax inactivity over the next decade has been attributed to concerns about interstate cigarette bootlegging in response to large tax-induced discrepancies in states' retail cigarette prices.[10] Consistently rising prices again since 1982 have been associated with increased antismoking sentiment in state and federal legislatures.[4]

To represent the assumption that the pattern of cigarette price was a function of the campaign, the dotted line treats price as if it had been constant (in real terms) in the years after 1963. This permits an assessment of the consumption effects of price fluctuations possibly produced as a result of the campaign. In contrast, actual experienced prices are reflected in the dashed line. The gap between the solid line (actual consumption) and dashed line (estimated consumption, actual prices) can be interpreted as a measure of the "pure publicity effect" of the campaign, while the gap between the dashed line and dotted line (estimated consumption, constant prices) measures the consumption impact of changing prices.

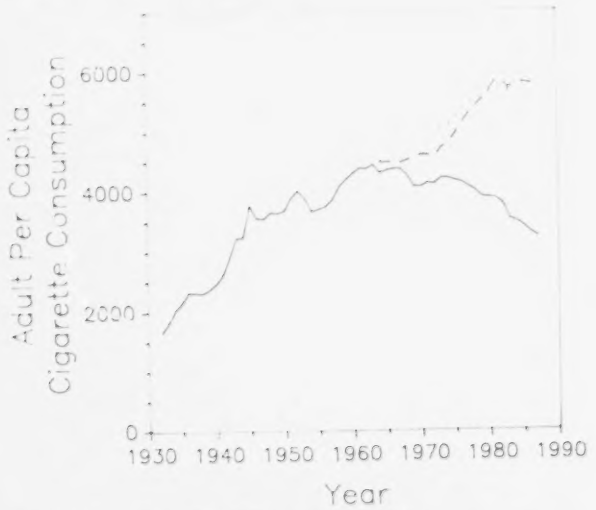

FIGURE 1—Adult per Cap. Cigarette Consumption
Solid line = actual consumption; dotted line = consumption predicted in absence of the antismoking campaign, with price held constant; dashed line = consumption predicted in absence of the campaign, with actual prices experienced

To the extent that the latter is attributable to smoking-and-health concerns of legislators, it constitutes a measure of price-related campaign-induced changes in consumption.

Each of the estimated lines exhibits a generally increasing pattern of consumption over time, in contrast to the pattern actually experienced. The analysis indicates that in 1987, per capita consumption would have been 79 to 89 per cent greater than the level actually experienced, depending on whether price changes are treated as independent of the campaign or as a function of it. The small difference suggests that, by 1987, price fluctuations contributed to decreased consumption, but to a much smaller degree than the "publicity effect."

Smoking Prevalence in Age- and Sex-Specific Cohorts

Results of the analysis of cohort smoking prevalence are presented in Tables 1 and 2 for men and women, respectively. Each cell records reported smoking prevalence for the relevant birth cohort and the relevant year, from 1964 through 1985, and the estimate of the smoking rate that would have been expected each year in the absence of the antismoking campaign.

To illustrate the nature of the findings, Figures 2 and 3 plot the numbers in Tables 1 and 2, as well as pre-1964 prevalence estimates, for two representative cohorts, one male and one female. The gap between the solid and dashed lines constitutes a measure of the impact of the campaign on smoking prevalence for these two birth cohorts.

The data in Tables 1 and 2 indicate that all 12 of the age-sex birth cohorts experienced substantial quitting, or non-initiation of smoking, as a result of the antismoking campaign. By 1985, the estimated gap between actual (reported) prevalence and that which would have been anticipated in the absence of the campaign ranged from a low of six percentage points for the eldest female cohort to a high of 28 percentage points for the youngest males. The percentage point gap is larger for each male cohort than for the same-age female cohort. For women, the percentage point gap in 1985 is larger as one moves from the older to the younger birth cohorts. For men, the gap is smallest for the oldest cohort and largest for the youngest; it is similar for the remaining four cohorts.

The "expected prevalence" figures indicate that a majority of each of the four youngest male cohorts would have been expected to be smokers in 1985 in the absence of the campaign, including two-thirds of men born 1951–60. In fact, fewer than 40 per cent of each cohort reported themselves to be smokers that year. Similarly, in the absence of the campaign, smoking prevalence in the four youngest female cohorts would have been expected to include a majority or near-majority of the women (44 per cent for the 1921–30 birth cohort to 54 per cent for the 1951–60 cohort). Yet each of these cohorts reported prevalence rates of either 27 per cent (1921–30 cohort) or 32 per cent (1931–60 cohorts).

Multiplied by their respective cohort populations, the 1985 reported prevalence figures indicate a total smoking population that year of 56 million Americans born between 1901 and 1970. In the absence of the campaign, the cohort analysis indicates that there would have been 91 million smokers. (The 1961–70 birth cohorts were added to the analysis for this purpose, with prevalence figures taken from the 1985 NHIS. "Expected" prevalence was assumed to be the same as that of the 1951–60 cohorts in 1975.)

Deaths Postponed by Campaign-Induced Decreases in Prevalence

Table 3 presents estimates of deaths postponed for each of the 12 age-sex cohorts identified in Tables 1 and 2, for the

period 1964 through 1985. The estimated total number of deaths postponed as a result of campaign response is 789,200. Of these 112,400 occurred in 1985 alone (not shown in table). The distribution between men and women and across birth cohorts is seen in the individual cells of the table. All told, the 789,200 postponed deaths represented a savings of 16.3 million life-years, an average of 20.6 years per death postponed.

Between 1964 and 1985, Americans born between 1901 and 1960 experienced an estimated 5.7 million smoking-related deaths. In the absence of the campaign, 6.5 million deaths would have been expected. The estimated 789,200 deaths postponed or avoided represented 12 per cent of the anticipated mortality toll.

Table 4 indicates that 2.1 million deaths will be postponed between 1986 and the year 2000 as a result of campaign-induced nonsmoking that occurred through 1985. The data in the table reflect the distribution between men and women and across birth cohorts.

Aggregate results of the sensitivity analyses for the two periods (1964–85 and 1986–2000) are presented in Table 5. Although they reduce the magnitude of estimated deaths postponed, the essential qualitative finding of the study is robust: as a result of campaign-related decisions to quit smoking or not to start, many hundreds of thousands of Americans have extended their lives an average of two decades each.

Discussion

Few people question the fact that the antismoking campaign has altered smoking behavior. Adult smoking prevalence has fallen from 43 per cent at the time of the

Surgeon General's first report on smoking to under 30 per cent a quarter century later; prevalence among men has almost halved. Per capita cigarette consumption has fallen annually since 1973, without exception, and is at its lowest level in 45 years; per capita tobacco consumption has reached its lowest level in a century.[4]

Yet such measures understate the impact of the antismoking campaign, since they miss the critical point that smoking prevalence and per capita consumption likely would have been rising in the absence of the campaign. For example, per capita consumption in 1987 was 27 per cent below the level that prevailed in 1963, the year prior to the Surgeon General's first report. But analysis of per capita consumption trends indicates that the 1987 value was actually less than half of what it would have been had the antismoking campaign never transpired.

This analytical perspective is most important in understanding the pattern of women's smoking. The relatively steady trend in adult female smoking prevalence from 1964 through the late 1970s, followed by relatively modest decreases in the 1980s, often has been interpreted as reflecting little response to the antismoking campaign. Yet as the cohort analysis demonstrates, in the absence of the campaign, women's smoking prevalence would have continued increasing, paralleling the diffusion pattern of smoking among men several decades earlier. As such, the stability of female smoking prevalence after the mid-1960s, at a level far below that attained by men, should be interpreted as behavioral response to the antismoking campaign.

Consistent with the observation that the campaign has affected smoking by men more than by women, the cohort analysis indicates that the percentage point gap between reported smoking prevalence and prevalence expected in the absence of the campaign is larger for each male cohort than for the same-age female cohort. Missed in this observation, however, is the comparability for men and women of the numbers of campaign-related quitters and noninitiators relative to the numbers of actual smokers. In 1985, this measure

TABLE 3—Deaths Postponed by Campaign-related Smoking Cessation and Noninitiation, 1964–85 (in thousands)

Birth year	Males	Females	Total
1901–10	103.6	16.7	120.3
1911–20	182.0	46.0	228.0
1921–30	182.7	59.6	242.3
1931–40	83.2	22.7	105.9
1941–50	44.0	15.5	59.5
1951–60	29.0	4.2	33.2
Total	624.5	164.7	789.2

of relative quit-and-nonstart rate—the ratio of the percentage point gap to actual prevalence—indicates little difference between males and females.

Growth in the gap between reported and expected smoking prevalence as one moves from the older to the younger cohorts, especially among the women, is consistent with the conventional wisdom that decisions not to start smoking are easier than decisions to quit. Decisions concerning the initiation of smoking occurred after 1964 for many members of the two youngest cohorts and well before 1984 for the older cohorts.

The peak rate of prevalence of the youngest cohort of males (42 per cent in 1980) makes this cohort the first group of men born during the 20th century never to have included a majority who were smokers. Supportive of the large gap found between this cohort's reported prevalence and the estimate of prevalence in the absence of the campaign are data on the peak prevalence of each of the older cohorts reported by Harris[11] [and unpublished data]. In the space of a single 10-year period, peak prevalence fell 16 percentage points, from 58 per cent to 42 per cent (for the 1941–50 and 1951–60 birth cohorts, respectively). In the span covered by three 10-year birth cohorts, the maximum percentage of men smoking fell by almost 30 percentage points (from 70 per cent for the 1921–30 cohort). Preliminary data from the 1987 National Health Interview Survey, combined with other NHIS data from the 1980s, suggest that the peak prevalence for the cohort of males born 1961–70 may represent a further decrease of as much as 12 or 13 percentage points, to a rate of 29 to 30 per cent.

The 70 per cent peak prevalence rates attained by the 1911–30 male cohorts suggest that the expected peak prevalence figures for males in Table 1 may be conservative. This perception is reinforced by recognition that the 1921–30 cohort achieved its peak rate of smoking in 1953, the year of the first major public smoking-and-cancer scare, and that the succeeding cohorts reached peak smoking age during periods of concern about the health consequences of smoking.

In this context, had women's smoking patterns eventually mirrored those of men approximately three decades earlier, the expected prevalence figures in Table 2 would have to be considerably larger than they are. As such, the gaps between reported and expected prevalence for women should be considered conservative measures of the impact of the antismoking campaign on women's smoking prevalence.

The deaths postponed analysis found that, by 1985, the 789,200 smoking-related deaths postponed or avoided represented 12 per cent of the smoking-related mortality that would have occurred in the absence of the antismoking campaign. In the predecessor to this study, the comparable figure through 1978 was 5 per cent.[3] The life-savings attributable to the campaign will continue to rise in the coming decades, both in absolute terms and as a fraction of total smoking-related mortality, as the cohorts most responsive to the campaign reach the ages at which smoking claims its greatest toll; in the more immediate future, campaign-related life-savings will also rise as older cohorts achieve the health benefits of long-term abstinence from smoking. This is demonstrated by the estimate of 2.1 million deaths postponed between 1986 and the year 2000 among those who had quit smoking or not started through 1985. The benefits of the campaign through 1985 alone substantially understate the long-term health dividend of campaign-induced behavioral changes that have already taken place.

TABLE 4—Deaths Postponed 1986–2000 by Campaign-related Smoking Cessation and Noninitiation through 1985 (in thousands)

Birth year	Males	Females	Total
1901–10	18.8	5.9	24.7
1911–20	194.6	83.8	278.4
1921–30	429.5	162.6	592.1
1931–40	315.3	128.6	443.9
1941–50	290.5	109.8	400.3
1951–60	241.7	76.3	318.0
Total	1490.4	567.0	2057.4

TABLE 5—Sensitivity Analyses

Sensitivity Test	Deaths Postponed (thousands) 1964–1985	1986–2000
1 Reduce excess smoker mortality ratios by 50%	519.8	1,416.1
2 Increase ex-smoker mortality ratios by 25%	581.1	1,876.5
3 Reduce campaign-induced quitters and noninitiators by 25%	592.8	1,547.7
4 Allow 50% recidivism among 1- and 2-year quitters and noninitiators	406.0	1,044.8

The analysis concluded that men have realized a much greater collective health benefit from their responses to the antismoking campaign than have women. This finding reflects more men than women having quit and not initiated smoking as a result of the campaign, and women having lower death rates and smoker mortality ratios than men. As women's smoking behaviors have approached those of men in recent years, the disparity between male and female smoker mortality ratios has diminished.[4] As such, this study's conservative assumption about women's smoker mortality ratios may have produced an underestimate of the health benefit of the campaign for women. Particularly in the younger cohorts, if women respond to the relatively new emphasis on the health consequences of their smoking,[12] the male-female differential of premature deaths avoided would be expected to decrease in the future.

The analysis of deaths postponed presents an incomplete picture of the health consequences of the antismoking campaign because it ignores the smoking-related morbidity and disability avoided. Moreover, it does not address directly one of the major behavioral impacts of the campaign: the shift from the unfiltered cigarette of the 1940s and '50s to filtered cigarettes and, more recently, to the low tar and nicotine (t/n) product.[4]

On the surface, this profound change might appear to represent a positive contribution to diminishing the toll of smoking. Yet recent evidence indicates that smokers compensate for reduced nicotine yields, often unconsciously, by such methods as smoking more cigarettes, inhaling more deeply, taking more puffs per cigarette, and blocking air ventilation holes in the filters.[13] Low-yield cigarette smokers are also exposed to additives that may introduce new health risks.[14] Further, the availability of filters and low-yield cigarettes may have encouraged many smokers to continue smoking when they otherwise would have quit. It is also possible that they have encouraged certain groups to start smoking in larger numbers, perhaps most notably young

females.[15] Each of these possibilities implies increases in smoking-related morbidity and mortality relative to that which would have occurred in their absence. As such, the net health consequences of changes in the cigarette product are unknown.

The most obvious concern about smoking is the continuing population of more than 50 million smokers. While, in the absence of the campaign, the number of smokers today would exceed 90 million, the remaining population of smokers assures that the enormous burden of smoking will persist into the 21st century. The fact that tens of millions continue to smoke, when the vast majority of them wish that they did not, illustrates the tenacious grip that nicotine places on its users.[14] This sobering reality places the impressive successes of the antismoking campaign in context, but it does not diminish them.

APPENDIX A

Cohort-Specific Procedures to Estimate Smoking Prevalence in the Absence of the Antismoking Campaign

The text explained the basic procedure for estimating cohorts' smoking prevalence rates in the absence of the antismoking campaign. For the two oldest male cohorts and for each of the female cohorts, deviations from the basic procedure were required. Additional minor adjustments were also required for the most recent years of the study.

For the more recent years of the study, comparison cohorts often reached comparable ages *during* the antismoking campaign. For example, the three comparison groups for the 1951–60 male cohort were the 1911–40 cohorts. To use the 1931–40 cohort in estimating the 1951–60 cohort's expected prevalence in 1984 and 1985 would place the former at comparable age in 1964 and 1965, the first two years of the campaign. Thus, for these two years, the prevalence changes of the two older cohorts alone were employed. In general, whenever a comparison cohort was of comparable age during the campaign, it was dropped from the analysis and the remaining one or two cohorts' prevalence changes were used.

When adequate comparison groups were not available, cohort-specific ad hoc procedures were adopted. In the instance of the 1921–40 male cohorts, this was needed only to estimate expected prevalence in 1984 and 1985. In both cases, the average decrease of the three preceding years was used.

For the 1911–20 male cohort, the basic procedure was followed through 1978 (using only the 1901–10 cohort as the comparison group, and making minor adjustments to compensate for the problem of understatement bias discussed by Harris[11]). Thereafter, expected prevalence was decreased 0.924 percentage point per year, the average of the annual declines from 1950–69 for the 1901–10 cohort.

The 1901–10 male and female cohorts had no useful comparison groups, since retrospective reporting of smoking histories in 1978 by people born before 1901 produces a significant underestimation bias[11]; in addition, the smoking histories of these earlier generations were not "models" for successor cohorts. Thus, for 1964–78, the expected prevalence rates were estimated by taking an arbitrary reduction of 50 per cent in the reported percentage point decrease in the rate of smoking. For the men, for expected prevalence after 1978, no additional differential change was assumed; i.e., an annualized rate of decline was selected to make the gap between expected and reported prevalence the same in 1985 as it was in 1978. For the women, a three-point decline between 1978 and 1985 was assumed, as it was for the 1911–30 female cohorts during these years. This decline was more gradual than for the same-age men, but the men's prevalence figures (both reported and expected) were higher than the women's in all cases.

For the earlier years (1964–78), there was no useful comparison group for the 1911–20 female cohort, since their smoking behavior differed radically from that of their predecessors, among whom smoking was quite rare. Arbitrarily, the cohort's 1956–63 smoking rate (37 per cent) was continued through 1967 and then decreased at a decelerated rate compared to the decline in reported smoking prevalence.

For the 1921–30 female cohort, given the emergence of the women's liberation movement, with its smoking manifestations, we assumed a continuing gradual increase in smoking prevalence through 1971, at which point a peak rate of smoking 49 per cent was assigned. For the remaining years, a very gradual rate of decline in expected prevalence was assumed.

For the three youngest female cohorts (born 1931–60), the basic estimation method was employed for the years 1964–78, subject to a slight modification: we assumed that the intercohort upward trend in peak smoking prevalence would have led these cohorts, in the absence of the antismoking campaign, to reach maximum smoking rates slightly above 50 per cent. This seemed a conservative assumption, given that actual peak prevalence for males of earlier cohorts exceeded 60 (and even 70) per cent.

For the years after 1978, the basic method did not apply, for lack of adequate comparison groups. Each of these three female cohorts was treated differently, reflecting their age differences. For the eldest (1931–40), expected prevalence was decreased by a total of two percentage points. Same-age males' expected prevalence fell by seven points but remained higher (at 54 per cent) in 1985 than that of the females (49 per cent). The more gradual decline among women seemed appropriate in light of the later diffusion of smoking among women and the later age of peak prevalence for this cohort.

For the 1941–50 female cohort, expected prevalence was held constant at 52 per cent during 1979–85. For the same-age males, expected prevalence fell slightly (64 to 60 per cent). Again, the later diffusion of smoking among women and the later age of actual peak prevalence made this assumption seem reasonable and conservative, since expected prevalence generally remained about 10 points below that of the same-age males.

For the youngest group of women (1951–60), expected prevalence growth of five points from 1978 through 1985 was assumed, equaling the expected prevalence growth for the same-age men and taking expected prevalence to 54 per cent, fully 12 percentage points below that of the same-age men.

Since, of necessity, many of these patterns of expected prevalence involved arbitrary judgments, their overall reasonableness was assessed by aggregating them and comparing them with the estimates of adult per capita consumption described in the text. This procedure suggested that the assumed patterns are reasonable in their representation of smoking prevalence trends in the aggregate. Obviously, the procedure cannot be used to determine whether individual cohorts' patterns are reasonable.

The major use of this cohort analysis, in evaluation of the number of deaths postponed as a result of campaign-response, includes a sensitivity analysis in which the gaps between actual and expected prevalence are diminished by 25 per cent. As such, the principal qualitative conclusions drawn

from the analysis of prevalence effects of the campaign are unlikely to be affected by possible misjudgments in evaluation of expected prevalence rates.

A few additional details on the estimating procedures, including explanations of why they are believed to be conservative, are presented in the appendix to the predecessor study[2] and in a document available from the author on request.

APPENDIX B

Adult per Capita Consumption Regression

The per capita consumption regression results are as follows:

$$C_t = -3565.2 - 7.83^{*}P_t + 0.74^{*}C_{t-1} + 1390.7^{*}Y_t - 153.66^{**}D53_t - 279.37^{*}D54_t - 181.36^{*}D64_t - 158.58^{**}D68_t - 278.17^{*}D69_t - 140.63^{**}D70_t - 23.92^{*}NSTATES_t \quad R^2 = .976$$

[* $p < .01$; ** $p < .05$]

where —C_t is adult per capita cigarette consumption in year t (mean = 3944)

—C_{t-1} is lagged consumption, which captures the effect of addiction

—P_t is relative real cigarette price in year t (index with $P_{1967} = 100$; mean = 92.32)

—Y_t is the natural logarithm of the last two digits of year t and reflects increases in the smoking population due to the diffusion of the behavior, particularly among women, and increases in smokers' daily consumption levels (mean = 4.18)

—$D53_t$, etc., are dummy variables, for the years indicated by the digits (except for $D54_t$), which provide estimates of the impact on consumption during these years of major antismoking activity (each = 1 in the year indicated by the digits, 0 otherwise)

—$D54_t$ is 0 before 1954 and $0.5^{(t-1954)}$ in 1954 and thereafter, a dummy which equals 1 in 1954 and has a continuing, though rapidly diminishing, additional effect that reflects additional publicity through the mid-1950s

—$NSTATES_t$ is the number of states having smoking restriction laws in effect in year t, a proxy measure for the effectiveness of the nonsmokers' rights movement (mean = 20.19)

The variables and data sources are identical to those used in the previous study,[1] except that the proxy measure of the success of the nonsmokers' rights movement in the earlier study was the percentage of the adult population residing in states with laws restricting smoking in public places, calculated by the author. The new variable was preferred because it comes from an independent source[16] (updated by the Office on Smoking and Health).

As noted in the text, findings with respect to the significance of individual variables are qualitatively identical to those reported in the previous study. The relatively small differences in the estimated coefficients in the two studies primarily reflect the addition of nine years to the period studied. The most striking difference reported in the Results section is the apparent reduction (in absolute value) in the price elasticity of demand from −0.37 to −0.2. While this might reflect a real change in the elasticity, representing a smoking population that is older and more addicted, it could also simply reflect the vagaries of time series analysis. Both figures are within the range of price elasticities found in other studies.[4]

The Results section also reports the strong inverse correlation between consumption and growth in the number of states with laws restricting smoking in public places. As observed in the previous study, this correlation should not be interpreted as implying that passage of nonsmokers' rights laws leads to reductions in cigarette consumption.[1] In fact, a new econometric study has concluded that the direction of causality might be the opposite: that is, decreases in consumption may be causing the growth in nonsmokers' rights legislation.[17]

Readers interested in further details on the interpretation of the regression results should consult the previous paper.[1]

International Comparisons of Trends in Cigarette Smoking Prevalence

JOHN P. PIERCE, PhD

Abstract: Data on smoking prevalence since 1974 are presented for the United States, Canada, Great Britain, Australia, Norway and Sweden. During this period, sex-specific prevalence has decreased in all the countries studied, with the exception of Norway, where women showed an increase. There was also a considerable decline in uptake of smoking by the young over this period, suggesting that the observed decline in prevalence is likely to continue. In the United States, the rate of decline in adult smoking prevalence has been linear. This linear pattern is probably similar in prevalence in most other countries studied, with the notable exception of Australia, which demonstrated no change for the majority of the period.

Among the six countries studied, the United States had neither the lowest smoking prevalence nor the fastest rate of decline over the period. Differential patterns of change infer that the successful public health interventions in some countries are not being applied in others. While the lack of change in Australia prior to 1983 is surprising, this was followed by a sizable drop in smoking prevalence for both higher and lower educational groups in conjunction with the introduction of mass media-led antismoking campaigns. Most of the other countries report an ever increasing gap in prevalence between higher and lower educational groups. These findings suggest that all countries might benefit from a greater exchange of antismoking ideas and public health action. (*Am J Public Health* 1989; 79: 152–157.)

Introduction

It is now over 25 years since the first major authoritative reviews of the serious health consequences of smoking[1,2] appeared in the public health literature. Since that time, the degree of public health mobilization and the type of activity have differed considerably across countries in the developed world. The most recent Surgeon General's report reviews progress in the United States over the last 25 years.[3] Of interest is how the United States has performed in comparison to other nations in achieving a reduction in the prevalence of smoking.

This paper reviews recent trends in reported cigarette smoking prevalence in six developed countries which have used different mixes of public health action to reduce cigarette smoking in their societies. Smoking trends across countries can be compared to identify those that have exhibited significantly higher rates of change or sudden shifts in prevalence. Either of these phenomena suggest the presence of a more effective intervention. If such occurs, then an analysis of public health action in that country could lead to suggestions for improvement in other countries.

In comparing cigarette smoking in differing countries, care needs to be taken to ensure that major sociodemographic differences that are associated with smoking do not confound the comparison. For the United States, the two most important differences are gender and education.[4,5] Accordingly, in this paper, I report smoking prevalence by each of these variables. Furthermore, as the proportion of each population taking up the habit is a crucial variable affecting future smoking prevalence,[6] I report a measure of sex-specific uptake for each country.

Methods

The major markers of behavioral change in smoking are the sex-specific adult prevalence, uptake of smoking by the young, and trends in smoking behavior in different educational categories. The goal measure of adult prevalence in this paper is the prevalence of smoking in those aged 20 years and over. As in the trend analyses for the United States,[3,4] uptake of smoking is indicated by the proxy variable "prevalence in age 20 to 24 years." The advantage of this measure is that differences due to variations in wording (such as daily smoking or any smoking) should be minimized; at least in the United States, 90 per cent of smokers report starting to smoke regularly before age 21.[3] This proxy for uptake will give a lagged estimate of what is actually happening by as much as five years.[4]

Details of data collection procedures and definitions for these two variables are presented below for each of the six countries. As educational level and education categorization of citizens in different countries differ considerably, this variable is presented separately to allow cross-cultural comparisons of categorizations.

United States

In the United States, the National Center for Health Statistics undertakes a regular household survey on the health practices of the nation. Since 1974, there have been regular smoking supplements to these surveys which report self-reported smoking behavior on a representative random sample of respondents. Smoking status was defined from two questions: "Have you smoked at least 100 cigarettes in your entire life?" and "Do you smoke cigarettes now?"[7] In the years previous to 1974, similar smoking data were obtained, often from another (proxy) adult living in the same household; this methodological difference is the reason for starting these trends in 1974. The response rate for the tobacco supplement has been reported as varying between 87 and 90 per cent.[4] Comparison of estimates of consumption from self-reported smoking with estimates from tax data[8] demonstrates a consistent 30 percentage point difference between the two estimates. Biochemical testing in community studies[9,10] suggests that this difference is not a result of people misreporting their smoking status.

Great Britain[11]

The Social Survey Division of the Office of Population Censuses and Surveys in Great Britain has conducted an annual General Household Survey since 1974. Sample size for these surveys has been between 12,000 and 14,000 households. Interviews are sought with all members of the household over 16 years of age and, where this is not possible, proxy interviews are accepted from a near relative.

Pierce, PhD, Chief, Epidemiology Branch, Office of Smoking and Health, 5600 Fishers Lane, Rockville, MD 20857. This paper, invited by the editor, was accepted for publication October 25, 1988.

INTENTIONAL
BLANK

This has occurred in approximately 5 per cent of households. Responses have been obtained from 81 per cent to 84 per cent of households in each survey year. Questions on smoking habits were included on each survey from 1972 to 1976 and every second year thereafter. Cigarette smoking status is defined from responses to the following questions: "Do you smoke cigarettes at all nowadays?" "Have you ever smoked cigarettes regularly?"

Other surveys have been commissioned regularly by the Tobacco Advisory Council and the Office of Population Censuses and Surveys. The first set of surveys are undertaken annually on quota samples of approximately 10,000 people. These data are adjusted to overcome differences in estimates between the self-reported and the tax data.

Canada[12]

Statistics Canada is responsible for an annual Labor Force Survey which covers the civilian non-institutionalized population 15 years of age and over from the 10 provinces of Canada. In the survey, 56,000 dwellings are sampled each month with sub-samples being interviewed each month for six months in a panel design. The Smoking Behavior of Canadians Survey has been conducted as a supplement to the Labor Force Survey; the sample was approximately 31,000 individuals in 1986 with a reported response rate of 95 per cent. Proxy respondents are accepted and smoking status of individuals is decided from responses to the following questions: "Has (the chosen respondent) ever smoked cigarettes, cigars or pipe?" "At the present time, does (the chosen respondent) smoke cigarettes?" "At the present time, does (the chosen respondent) smoke cigarettes regularly?" In 1986, proxy respondents made up 30 per cent of the sample.

Australia[13,14]

Surveys of tobacco smoking in Australia have been commissioned five times since 1974 by the Anti-Cancer Council of Victoria using the national commercial pollster, Roy Morgan Research.[9] Cluster samples of 10 interviews were obtained by approaching consecutive households starting from a stratified random sample of houses drawn from electoral rolls. Data were collected from respondents ages 14 years and over. These surveys report a 40 per cent non-response rate, half of which comes from those we were unable to contact and the other half from refusals to participate in the well-known weekly "omnibus" survey on consumer products. The representativeness of the sample was demonstrated by comparing demographics obtained for subdivisions with those obtained from published Census data.[10] Validation of self-reported smoking was shown by comparison with saliva cotinine on large sub-samples at two points in time.[4]

Respondents were shown a card and asked to classify themselves into one of 10 smoking categories made up from current smoking of the different combinations of cigarette, cigar, and pipe smoking. Smoking prevalence used in this paper is derived from the following categories "Smoke only cigarettes" "Smoke cigarettes and also cigars/pipe."

Scandinavian Countries

Each year, in each of the Scandinavian countries, surveys are conducted of nationwide, representative population samples between the ages of 18 and 70 years drawn from a population registry. In Sweden,[15] in-person household interviews on samples of approximately 2,000 people were conducted from 1976 to 1983 with mailed questionnaires being used from 1984 to 1987. Between 1976 and 1983, response rates varied from between 80 and 82 per cent. Since 1984, a direct random sample of equivalent size drawn from the nationwide registry received a mailed questionnaire with a letter emphasizing the importance of self-completion and guaranteeing anonymity. Non-respondents are given two mailed reminders after which a random 50 per cent are interviewed by telephone. The estimated weighted response rate has varied between 85 and 90 per cent. Each of these countries uses the questions recommended by the World Health Organization to categorize smokers: "Have you ever smoked?"; "Have you ever smoked daily for six months or more?"; "Do you now smoke daily, occasionally or not at all?"; "What kinds of smoking material do you use (cigarettes, other)?"

The Norwegian Central Bureau of Statistics conducts annual in-person household interviews on a representative sample (approximately 2,500 each year) of the Norwegian population between 16 and 74 years of age.[16] Smoking questions are the same as those used for Sweden.

Educational Socioeconomic Categorization

Educational level of smokers is reported for each country except the United Kingdom which prefers to report occupationally based categories of social class or major socioeconomic group. The Appendix presents approximate equivalent categories for each country. In all countries there is a natural division of education between secondary or high school level and post-secondary. However, the division of post-secondary into college graduate and less than college graduate has varied over the years in differing countries. Similarly, the actual level of certification for satisfactory completion of high school education has varied within a given country over time. Accordingly, caution should be used in interpreting these data. The data are satisfactory for assessing whether there is a smoking differential across educational categories and for identifying whether there has been a differential trend across such categories as has been suggested in the United States.[4]

Analysis

For the United States data, prevalence estimates from 1974 to 1985 were weighted to reflect the US population and age standardized to the 1985 age distribution. Standard errors for prevalence estimates were adjusted for sampling design by using variance curves provided by the National Center for Health Statistics.[4] The change in these data was equally well fit by both a linear and a logit model[6]; for simplicity, the linear model is preferred. Weighted least squared regression analysis was used to calculate the average yearly change in prevalence over the period. The effect of age adjustment and using weighted analysis altered the estimated yearly change by less than 0.05 per cent per year.

For other countries, the reported prevalence has been weighted to reflect the population. Neither age standardization nor weighted analyses were possible from the available data. Using the linear pattern in the United States as justification, a simple linear model was fitted to the data from each country to arrive at an estimated change per year. Without the relevant standard errors and with age adjustment of the population for different years, this analysis must be considered to be crude and should only be used to identify differences which are orders of magnitude away from those reported for the United States.

Results

Smoking Prevalence

By 1974, smoking prevalence in Adult males in the United States, Australia, and Canada was in the low 40s (Table 1). These levels were considerably lower than those for Great Britain and Norway where over half of the adult male population was smoking. However, by the mid 1980s, with the exception of Norway, all six countries reported male smoking prevalence in the low 30s. For the United States, a linear model fits the 1974 to 1985 data extremely well (R^2 = 0.97) and smoking prevalence has been decreasing each year by 0.91 of a percentage point (standard error 0.03). According to this model, the 1987 estimate is 31.7 which is exactly the same as the observed estimate. There was considerable variation in the average rate of change in smoking prevalence calculated for the other countries. The estimated change was largest in Great Britain at 1.35 percentage points per year. Canada, Norway, and Sweden report changes of the same order of magnitude as the United States. Among Australian males, the linear model indicates that there has been little change in smoking prevalence. The observed data suggest that minimal change occurred between 1974 and 1983. However, there was a drop of six percentage points between 1983 and 1986, suggesting that the linear model is inappropriate to describe smoking trends among Australian males over this period.

In contrast to males, female smoking in 1974 had not risen to much over 30 per cent of the population in any country except Great Britain (Table 2). By the mid 1980s, smoking prevalence had declined in adult women in all countries except Norway and perhaps Australia. In the United States, the linear model fitted to the 1974 to 1985 observed data explained 88 per cent of the variation and the change per year was 0.33 per cent (SE 0.06). According to the linear model, the 1987 estimate should have been 26.9 per cent, 0.1 per cent higher than that observed. This rate of change is lower than that estimated for Great Britain, Sweden, and Canada. While the rate of change in almost all countries is well below that reported for males, by the mid 1980s in all countries except Sweden, there were still fewer female than male smokers.

Uptake of Smoking

With the exception of the United States and Sweden, the prevalence of smoking among males from 20 to 24 years of age approximated 50 per cent in the mid-1970s (Table 3). During the mid-1980s, however, there was a major decline in the uptake of smoking in the United States, Australia, and Canada. In the United States, the linear model explained 75 per cent of the variation in the observed 1974 to 1985 data. The rate of decrease was 1.03 percentage points per year (SE 0.27). According to this model, the 1987 figure should be 31.3 which is slightly higher than the observed 31.1 per cent. Considerable variability was again evidenced in the Australian data with a high 56.5 estimate for 1980 which meant that the slope of the regression line was close to zero.

Prevalence of smoking in young females (Table 4) varied considerably between countries in the mid-1970s with the highest rate of smoking occurring in Scandanavia. Thereafter, higher estimates of smoking prevalence were recorded in almost all countries for at least one year before prevalence started to decrease. In the United States and Australia, the mean change over the period was positive. In the case of the United States, the linear model had a rate of change of +0.11 percentage points per year (SE 0.27). Smoking prevalence in 1987 was 28.1 which is substantially lower than the estimate from the linear model. In all countries except Australia, the mid-1980s estimate was below that of 1974. In nearly all countries, once the prevalence began to drop it did so at a rate equal to or greater than that of young males over the whole period. This was particularly evident in the Canadian data.

Smoking by Educational/Socioeconomic Level

In each of the countries studied which reported smoking data by educational level, the prevalence of smoking decreased with increasing education (Table 5). Furthermore, there was approximately a twofold difference in smoking prevalence between the highest and lowest educational categories.

TABLE 5—Trends in Cigarette Smoking Prevalence by Education Level, 20 Years of Age and Over

Educational Level	United States	Australia	Canada	Norway††	Sweden†

††20–70 years only
SOURCES: United States: Pierce, *et al.*[5]; Australia: Hill, personal communication; Canada: Millar[16]; Norway: Lund, personal communication; Sweden: Ramstrom, personal communication

A similar trend was observed across socioeconomic groups in the United Kingdom. In 1984, smoking prevalence in professional men and women was 17 per cent and 15 per cent, respectively. For males, smoking prevalence rose inversely with socioeconomic category to a high of 49 per cent for the unskilled, manual category. Smoking prevalence in women was in the high 20s for non-professional white-collar workers and in the high 30s for all workers in lower socioeconomic categories.

Trends in Smoking by Educational Level

Trend information for the highest and lowest categories of education are presented in Table 6 for four countries. In the United States, the linear model for college graduates explained 92 per cent of the variation in the observed data. The estimated reduction in smoking prevalence per year is 0.91 percentage points (SE 0.13). This model predicted that the 1987 prevalence would be 16.5 per cent which was slightly higher than the observed 16.3 per cent. For those with less than high school education, the linear model accounted for 85 per cent of variation in the data. The annual rate of decline was 0.19 percentage points (SE 0.03). This model predicted that smoking prevalence in this group would be 33.8 percent in 1987, considerably lower than the observed estimate of 35.7 per cent. Thus, the difference in the rate of reduction between the highest and lowest education levels was at least ninefold. A twofold difference was reported in Canada and a threefold difference in Norway. Australia was the only country in which smoking prevalence decreased approximately equally in both the highest and lowest categories.

Discussion

Trends in smoking prevalence have been compared for six countries known for their public health action to reduce smoking in their societies. In each country, there was a marked difference in the rate of change between males and females as the historical gap between the sexes diminishes.[4] This differential rate of change might reflect a real difference between the genders in response to the public health message. However, a recent analysis of the proportion of ever smokers who have quit (quit ratio) in the United States[4] suggests that the explanation lies in differences in age-specific cigarette smoking levels that result from the historical patterns of smoking uptake, i.e., the cohort effect suggested by Warner and Murt.[17]

For both males and females in the United States, the decline in smoking prevalence between 1974 and 1985 oc-

curred at a constant rate and the linear model closely predicted the 1987 prevalence. The decline in prevalence for each sex could very well be linear also in Great Britain, Canada, Norway, and Sweden. While caution is needed in comparing smoking prevalences in any given year, the United States is at the low end of any comparison. The country with by far the lowest prevalence is Sweden, although this might be confounded by the substitution of other tobacco products such as moist snuff, cigars, and pipes.* Of all the sex-specific trends reported, only women in Norway demonstrated an increase in smoking prevalence.

The rate of change in prevalence was much higher in Great Britain than in other countries, although this was also associated with a high initial prevalence in that country. Although methodological differences prevent precise statistical comparison, it is probable that the rate of change was higher for both sexes in Canada than in the United States and higher for women in Sweden. For both genders in Australia, although the linear model suggested that smoking prevalence had not declined much, the data are consistent with the reported large drop in prevalence that occurred with the introduction of the mass media-led coalition campaigns in that country.[18,19]

There also has been a consistent decline in the uptake of smoking among males in the United States in recent years. The rate of this decline was surpassed only in Canada and Sweden, although the estimates for the latter are somewhat unstable from small sample size. Again, in Australia, data indicated no linear trend, although this maybe an artefact of small sample size and an abnormally high reading for 1980. Uptake in young females in the United States did not decline between 1974 and 1985, but the 1987 prevalence suggests that such a decline has started to occur. This decline was well under way in other countries with large decreases in prevalence noted in Canada, Sweden, Norway, and Great Britain, although in each case prevalence started from a much higher base than in the United States. For both males and females, with the exception of Sweden, the United States had the lowest rate of uptake.

In every country smoking is much more prevalent in the lower socioeconomic groups than in the higher ones. Between 1974 and 1987, in both the United States and Canada, there was a major and consistent yearly decrease in smoking prevalence in the highest educational category. The rate of change was much greater in the highest compared to the lowest educational category in every country except Australia. Change in smoking prevalence did not start in Australia until 1983, after which it declined equally in both the highest and lowest categories.

In summary, there has been a major decline in smoking prevalence in all the countries studied. Comparison between the countries suggests that in recent times, the United States has had neither the lowest prevalence of smoking nor the fastest rate of decline in smoking. In particular, the rate of decline has been higher in Great Britain and Canada. Lack of change in prevalence among the lower educated is a major barrier to further marked decreases in smoking prevalence in the United States. This suggestion that public health action is not affecting a very sizable proportion of the population is apparent in all countries except Australia. In that country, with its State-based mass media-led campaigns, an equivalent decline was seen in both the highest and lowest educational categories since 1983. However, the lack of change in smoking prevalence in Australia throughout the decade before 1983 may reflect the lack of a clear government focus for smoking and its related health problems. Before 1983, any public health action on smoking came from the voluntary health agencies. The marked change since 1983 reflected the decision by a number of key state governments to act unilaterally and set up well-funded mass media-led antismoking campaigns. Australia still lacks a national bureaucratic structure whose sole responsibility is smoking and health. It

*Ramstrom L. Personal communication.

is apparent that all countries can benefit from further cross-fertilization of ideas and public health actions between countries. Undoubtedly, there is already considerable contact between public health professionals, from different countries concerned with reducing smoking in their own societies. However, the performance of each country in reducing smoking prevalence over the last 10 years indicates that each country has room for improvement in its public health action and suggests that interventions may not be diffusing across countries as rapidly as is either possible or desirable.

The Influence of Smoking on Vitamin C Status in Adults

GORDON SCHECTMAN, MD, JAMES C. BYRD, MD, AND HARVEY W. GRUCHOW, PHD

Abstract: To further define the relation between smoking and vitamin C status, the dietary and serum vitamin C levels of 11,592 respondents in the second National Health and Nutrition Examination Survey (NHANES II) were analyzed. Smokers of 20 cigarettes daily had the lowest vitamin C dietary intake (79 mg, 95% CI: 73, 84) and serum levels (0.82 mg dl, 95% CI: 0.77, 0.86; 46.6 μmol L, 95% CI: 43.7, 48.8), while smokers of 1–19 cigarettes daily had decreased vitamin C intake (97 mg; 95% CI: 90, 104 mg) and serum levels (0.97 mg dl, 95% CI: 0.92, 1.03; 55.1 μmol L, 95% CI: 52.2, 58.5) compared to respondents who had never smoked (109 mg, 95% CI: 105, 113 and 1.15 mg dl, 95% CI: 1.11, 1.18; 65.3 μmol L, 95% CI: 63.0, 67.0, respectively). This inverse association between both intake and serum levels of vitamin C and smoking was independent of age, sex, body weight, race, and alcoholic beverage consumption. Following further adjustment for dietary vitamin C intake, the negative correlation between cigarette smoking and serum vitamin C levels persisted. The risk of severe hypovitaminosis C (serum levels ≤ 0.2 mg dl; 11.4 μmol L) was increased in smokers, particularly when not accompanied by vitamin supplementation (odds ratio 3.0, 95% CI: 2.5, 3.6). These data suggest that even though smoking adversely affects preferences for vitamin C rich foods, the inverse association between smoking and serum vitamin C levels occurs independently of dietary intake. (*Am J Public Health* 1989; 79:158–162.)

Introduction

Preliminary reports have indicated adverse affects of smoking on vitamin C metabolism[1,2] and more recent studies have confirmed that serum vitamin C levels are lower in cigarette smokers than non-smokers.[3–7] These observations suggest that smoking directly lowers serum vitamin C levels,[8] although other factors including gender,[4,9] age,[4,10] and ethanol consumption[11–13] have also been reported to influence serum vitamin C concentrations. However, since cigarette smoking is not independent of age, sex, or alcohol use,[14] the relation between smoking and vitamin C status requires evaluation controlling for these potentially confounding variables. Several previous reports have partially addressed these concerns by stratifying participants according to age,[7,15,16] sex,[15,16] and level of vitamin C intake.[15] Within each stratum, vitamin C levels were decreased in smokers, suggesting that the relationship may indeed be independent of these factors. A univariate analysis of the United States second National Health and Nutrition Examination Survey (NHANES II) was consistent with these findings, as serum vitamin C levels were lower in smokers for each level of dietary vitamin C intake.[17]

The purpose of this study was to better define the independent relationship between cigarette smoking and vitamin C status, while controlling for potentially confounding variables using multivariate statistical techniques on data from NHANES II, conducted from 1976–80. NHANES II is a comprehensive population survey which included serum vitamin C measurements and a detailed dietary questionnaire from which nutrient intakes were calculated in a sample of over 11,000 adults. The association of cigarette smoking with serum vitamin C levels was analyzed while simultaneously adjusting for variables which significantly influenced serum vitamin C concentrations including age, sex, race, dietary vitamin C intake, ethanol consumption, and body mass index (BMI). In addition, the impact of smoking on the risk of marginal or frankly deficient serum vitamin C levels was determined.

Methods

The NHANES II probability sample was selected so that population subgroups of special interest for nutritional assessment were oversampled. Among adults, the oversampled groups included persons over 60 years old and persons below poverty level. Sample weights were then computed for these subgroups so that the total sample closely estimated the noninstitutionalized civilian population. This sample weighting reflects the individual selection probability, adjustments for non-response, and poststratification adjustments. A complete description of the survey methods has been reported.[18]

Adults ages 18 to 74 years who attended a second examination visit following a preliminary interview were studied. However, respondents who did not have serum vitamin C concentrations measured (n=866), who did not record alcoholic beverage consumption (n=40), and who did not complete smoking histories (n=6) were excluded from the analysis. After these exclusions, 11,592 respondents remained eligible for the study. Appropriate sample weighting was used to adjust for possible non-response bias introduced because of failure to attend the second examination visit.[19] Those who attended the second visit but who were subsequently excluded (n=912) were similar to included subjects in the per cent who were male (46.6 vs 47.4 per cent), White (82 vs 89 per cent), currently smoking (32 vs 34 per cent), and in their mean age (46.7 vs 46.2 years).

Nutrient intakes were estimated from 24-hour recall interviews. Three-month food frequency reports provided recent intake of individual food items, including estimates for beer, wine, and liquor. Weekly frequencies of beer, wine, and liquor consumption were summed to estimate ethanol consumption. The use of vitamin and mineral supplements was determined by the question "Are you taking vitamins or supplements?" The vitamin content of supplements was excluded from the nutrient intake summaries and therefore the calculated vitamin C intake underestimates actual vitamin C consumption in those respondents taking supplements. For this reason, the use of supplements was included as a separate variable in the multivariate analysis assessing serum vitamin C levels.

NHANES II participants were originally divided into racial categories of "White", "Black", and "other". Individuals of Oriental extraction, American Indians, and Eskimos were listed in the "other" category and accounted for less than 1 per cent of the total study cohort; they were

included with Whites in this study. Body mass index (BMI) was measured as weight/height^2 (kg/m^2).

Serum vitamin C levels were measured in a central laboratory at the Centers for Disease Control (CDC) by the dinitrophenylhydrazine method.[20] Criteria from the Nutrition Canada Survey were used to classify risk of clinical scurvy.[21] Respondents with serum vitamin C levels of 0.2 mg/dl (11.4 μmol/L) or less were considered to be at high risk for clinical vitamin C deficiency (severe hypovitaminosis C), while those with serum concentrations of 0.4 mg/dl (22.7 μmol/L) or less were considered to be at marginal risk (marginal hypovitaminosis C).

Variance estimates were corrected for the complex sample design using the SUPERCARP program.[22] Multiple regression was used to determine the independent contribution of a variable to serum vitamin C levels, while simultaneously adjusting for all other variables.[23] An order of entry was determined using a stepwise regression model, however, regression coefficients were computed following the insertion of all variables into the model. For the regression equations, smoking status was categorized into six levels: never smoked, stopped for the previous year or longer (DC > 1 year), stopped within the past year (DC < 1 year), smoking less than 20 cigarettes daily (<1 PPD; mean 9.3 cigarettes), smoking 20 cigarettes daily (1 PPD), and smoking more than 20 cigarettes daily (>1 PPD; mean 35.1 cigarettes). This was done to compare serum vitamin C levels in cohorts of subjects who were currently smoking, had stopped smoking, or who had never smoked. In additional analyses, smoking status was also recorded as a continuous variable (i.e., number of cigarettes smoked daily). Odds ratios for smoking and nutrient supplements on the risk of hypovitaminosis C while controlling for possible confounding variables were determined by the Mantel-Haenzel procedure.[24,25]

Results

Table 1 shows univariate analyses for variables associated with both serum vitamin C levels and cigarette smoking prevalence. Serum vitamin C levels were significantly associated with gender, race, age, and body mass index. Males, when compared to females, Blacks when compared to Whites, and adults under the age of 60 years when compared with those over 60 had lower serum vitamin C levels and a higher prevalence of smoking. Heavier individuals (BMI > 27), on the other hand, had lower serum vitamin C concentrations and a lower prevalence of smoking. Higher ethanol intakes (>5 drinks daily) were associated with a higher likelihood of smoking, while a non-significant increase in vitamin C levels (p=0.09) was observed in those with more moderate consumption (1 to 5 drinks daily).

An inverse relation between cigarette smoking and dietary vitamin C intake is demonstrated in Table 2. The mean vitamin C intake for all smokers was 20% lower compared with non-smokers (86 mg, 95% CI: 83, 90 vs 108 mg, 95% CI: 106, 111 [not shown]). This decrease was particularly marked in individuals smoking 20 cigarettes daily. Smokers of less than 20 cigarettes daily had an intermediate vitamin C intake while individuals who stopped smoking for more than one year had a vitamin C intake (108 mg, 95% CI: 103, 113) similar to never smokers. This inverse association between smoking and dietary vitamin C intake persisted following adjustment for age, sex, race, ethanol intake, income and body weight.

TABLE 1—Dietary Vitamin C Intake, Serum Vitamin C Levels, and Smoking Frequency in Individuals by Category of Gender, Race, Age Tertiles, Body Mass Tertiles, and Alcohol Consumption

	N	Serum Vitamin C mg/dl* (95% CI)	Smokers (per cent)
Gender

In addition to decreased vitamin C consumption, smokers had serum vitamin C levels which were 24 per cent lower than non-smokers (0.87 mg/dl, 95% CI: 0.86, 0.89 vs 1.13 mg/dl, 95% CI: 1.12, 1.14; 49.4 μmol/L, 95% CI: 48.8, 50.5 vs 64.2 μmol/L, 95% CI: 63.6, 64.7 [not shown]). As shown in Table 3, smokers of 20 cigarettes daily had the lowest serum vitamin C concentrations (0.82 mg/dl, 46.6 μmol/L), while serum vitamin C levels were highest in individuals who had either stopped smoking for longer than one year or who had never smoked. The decrease in serum vitamin C levels observed in smokers persisted, even after adjusting for differences in dietary intake, age, gender, body weight, race, and vitamin supplementation. In multiple regression analysis, smoking status was the most important non-nutritive predictor of serum vitamin C levels, explaining more of the total variance than did gender, race, BMI, or age (Table 4). In additional analyses, smoking status was entered into the regression equation as a continuous variable defined as the number of cigarettes smoked daily. The order of entry and regression coefficients in these analyses were similar to those shown in Table 4 (i.e., when smoking was entered as a non-continuous variable).

with serum vitamin C levels for smokers and non-smokers are shown in Figure 1. The slope of the two lines is similar, with a consistent difference in serum vitamin C levels between smokers and non-smokers of approximately 0.2 mg/dl (11.4 μmol/L), independent of the level of dietary vitamin C intake. Using the regression equations, an additional 133 mg of dietary vitamin C was calculated to be necessary to increase the serum vitamin C level in smokers to the level found in non-smokers.

To test the hypothesis that smoking increases the risk of hypovitaminosis C, the frequency of low serum vitamin C levels occurring in smokers was compared with non-smokers. Of all smokers, 7.4 per cent had serum vitamin C levels of 0.2 mg/dl (11.4 μmol/L) or less compared with 1.9 per cent of non-smokers who had similar vitamin C levels. An additional 19.7 per cent of smokers had serum vitamin C levels between 0.2 mg/dl (11.4 μmol/L) and 0.4 mg/dl (22.7 μmol/L), compared with 8.2 per cent of non-smokers. Since further adjusting for BMI and age did not affect mean serum vitamin C levels, only gender, race, and dietary vitamin C intake were used as controlling variables to determine the risk of smoking on marginal or severe hypovitaminosis C. After adjusting for gender and race, risk ratios for smoking of 3.5 (95% CI: 2.9, 4.2) for severe, and 3.1 (95% CI: 2.8, 3.5) for marginal hypovitaminosis C were obtained (Table 5). Further adjustment for dietary vitamin C intake resulted in a minor reduction in the odds ratio.

Of the total sample, 37 per cent reported taking vitamin

or mineral supplements. The frequency of marginal hypovitaminosis C according to smoking and supplementation status is shown in Table 6. Smokers who did not take vitamin supplements had an 11.3 fold increased risk (95% CI: 9.6, 13.3) of marginal hypovitaminosis C compared with non-smokers who took supplements. Even smokers who took vitamin supplements were at increased risk of marginal hypovitaminosis C (odds ratio 2.5; 95% CI: 2.0, 3.1).

Discussion

Our analysis of the NHANES II data confirms that cigarette smoking is associated with decreased serum vitamin C levels. This association persisted despite correction for factors which independently affected serum vitamin C levels such as age, gender, race, and BMI. Dietary vitamin C intakes were lower in smokers than non-smokers, a finding which might potentially explain this inverse correlation. However, further adjustment for vitamin C consumption revealed that the association between smoking and serum levels was independent of dietary intake (Table 4). In fact, smoking status explained more of the total variance of serum vitamin C levels than did the self-reported dietary intake of vitamin C. Moreover, the increased risk of hypovitaminosis C in smokers was not substantially lowered when correcting for the decreased dietary vitamin C intake associated with smoking (Table 5). These observations suggest that cigarette smoking has an important influence on serum vitamin C levels which occurs predominantly via a mechanism independent of decreased dietary vitamin C consumption.

TABLE 5—Risk of Hypovitaminosis C in Smokers versus Non-smokers

	Unadjusted for Vitamin C Intake	Adjusted for Vitamin C Intake
Vitamin C Deficiency	Smoking Odds Ratio (95% CI)	Smoking Odds Ratio (95% CI)
Severe	3.5 (2.9, 4.2)	3.0 (2.5, 3.6)
Marginal	3.1 (2.8, 3.5)	2.8 (2.6, 3.1)

Unsupplemented subjects only.

TABLE 6—Combined Effect of Smoking and Vitamin Supplementation on Risk of Marginal Hypovitaminosis C

	Hypovitaminosis C Prevalence (%)	Risk of Hypovitaminosis C Odds Ratio (95% CI)*
Supplemented non-smokers	3.5	1.0
Supplemented smokers	9.8	2.5 (2.0, 3.1)
Unsupplemented non-smokers	14.5	3.9 (3.3, 4.7)
Unsupplemented smokers	35.7	11.3 (9.6, 13.3)

Inverse associations between smoking and vitamin C status have been previously reported. Most studies, however, have employed small sample sizes[1-5] or have been unable to control potentially confounding variables.[4,6,7] Pelletier stratified 4,500 Canadians participating in the Nutrition Canada National Survey into three categories of dietary vitamin C intake (0–30 mg, 30–100 mg, and over 100 mg) and analyzed serum vitamin C levels according to gender and age; an average 30 per cent reduction in serum levels were observed in smokers compared with non-smokers.[15] Ritzel, *et al.* determined that mean serum vitamin C levels were lower in smokers, independent of weekly citrus fruit consumption, in 4,053 healthy Swiss employees.[16] The risk of severe or marginal hypovitaminosis C was increased approximately threefold in smokers. Univariate analysis of NHANES II demonstrated a difference in serum vitamin C levels of 0.2 mg/dl (11.4 μmol/L) between smokers and non-smokers at each of six levels of dietary vitamin C intake.[17] These results are similar to the findings in this study using stepwise multiple regression to analyze the NHANES II data.

The lowered serum vitamin C levels in smokers could be due to either impaired vitamin C absorption or increased turnover. On the basis of studies measuring urinary vitamin C excretion in conjunction with the administration of known vitamin C intakes, Pelletier suggested the presence of impaired bioavailability but normal turnover of vitamin C in smokers.[26,27] On the other hand, Kallner, *et al.* measured vitamin C kinetics using radio-labeled ascorbic acid and demonstrated increased turnover in smokers but only small differences in absorption when compared to non-smokers.[28] Others have reported that smoking acutely increases urinary excretion of vitamin C,[29] also suggesting an accelerated metabolism in smokers. Interactions between vitamin C metabolism and a number of drugs have been described.[30,31] Identification of the responsible compound in tobacco smoke and the elaboration of its mechanism will require further study.

In this study, serum vitamin C levels were approximately 0.2 mg/dl (11.4 μmol/L) lower in smokers compared with non-smokers regardless of dietary vitamin C intake (Figure 1). Therefore, the impact of smoking to decrease serum vitamin C levels was proportionately greater in participants with initially low serum vitamin C levels. This resulted in a higher proportion of smokers with serum levels below the 0.2 mg/dl (11.4 μmol/L) or 0.4 mg/dl (22.7 μmol/L) range cutoffs for severe or marginal hypovitaminosis C. In this regard, the risk ratio for hypovitaminosis C was threefold greater in smokers when compared with non-smokers. Therefore, although the prevalence of severe and marginal hypovitaminosis C in NHANES II was low, certain subgroups, such as smokers not taking nutritional supplements, may be at substantial risk.

The significance of the increased risk of hypovitaminosis C produced by the interaction between smoking and serum vitamin C levels is not currently known. Although guidelines developed by the National Survey of Canada in 1973 suggested categories of high risk for serum vitamin C levels below 0.2 mg/dl (11.4 μmol/L), and of moderate risk for levels between 0.2 and 0.4 mg/dl [11.4 and 22.7 μmol/L],[21] the actual relation between low serum levels and clinical scurvy is not well defined. While serum levels in reported cases of scurvy are 0.4 mg/dl (22.7 μmol/L) or less,[32-34] individuals without clinical signs of scurvy may also have low serum levels.[35,36] However, because deficient vitamin C status has been associated with behavioral changes,[37,38] poor recovery from surgical procedures,[39] the presence of sublingual petechia,[40] and gingival disease,[41] and because the risk of overt scurvy is likely to be increased in this setting, the identification of individuals with hypovitaminosis C may have important implications. An assessment of the extent that hypovitaminosis C constitutes a true public health problem will require further studies to confirm that individuals with serum vitamin C levels below the cut-points used are truly at increased risk for adverse health outcomes.

The observed decrease in dietary vitamin C intake among smokers was unexpected. Although altered food preferences in smokers compared with non-smokers has been established,[42,43] a specific association of smoking with vitamin C intake is not well recognized. In the Caerphilly Heart Disease Study, smokers had a 22 per cent lower mean vitamin C intake compared with non-smokers,[44] similar to our findings in NHANES II. Our observation that vitamin C intake was lowest in individuals smoking 20 cigarettes or more daily, and that smokers who have stopped for greater than one year have intakes similar to individuals who have never smoked, suggest a specific aversive effect of smoking on vitamin C rich foods which may be reversible when smoking is discontinued. A more complete analysis from NHANES II of the effect of smoking on food preferences and vitamin intake will be reported separately.

Although an association between depressed vitamin C levels and smoking was determined to be independent of other potentially confounding variables, a cause and effect relationship cannot be assumed from this study. Prospective studies will be required both to prove that smoking directly affects vitamin C metabolism and to evaluate possible mechanisms. However, the cohort of participants who smoked less than 20 cigarettes daily had lower mean serum vitamin C levels than heavier smokers but higher than non-smokers, suggesting a dose-response effect. In addition, former smokers had higher serum levels than current smokers, indicating that the influence of smoking on serum vitamin C levels may be reversible. These observations suggest that the association between smoking and serum vitamin C levels may be causal.

This study is also limited by the methodological problems associated with estimating dietary intake in cross-sectional studies of free-living populations. Dietary recall of the preceding 24-hour period may not provide an accurate or representative assessment of current nutritional intake for an individual. However, this limitation is lessened when assessing the average intake of a group, since the group mean intake is less sensitive to day-to-day variability.[45] An additional shortcoming is that specific nutritional supplements were not systematically recorded and therefore were not included in the dietary analysis. This problem has been addressed in this study by either adjusting or stratifying for supplement use.

This analysis of NHANES II data confirms that cigarette smokers in the United States have lower serum concentrations of vitamin C than non-smokers, an association which persisted following adjustment for potentially confounding

factors. Because of these decreased levels, smokers had a three-fold increase in risk of marginally or severely deficient vitamin C status. Approximately 35 per cent of smokers had low serum levels placing them within one of these two categories. Although smokers taking vitamin supplements were also at increased risk of hypovitaminosis C compared with non-smokers, the prevalence of low serum vitamin C levels was much reduced in both smoking and non-smoking individuals taking supplements. This finding suggests that the increased vitamin C intake associated with vitamin supplementation may frequently prevent the low serum levels from occurring in smokers. As estimated by the regression curves in Figure 1, approximately 130 mg of additional dietary vitamin C daily would be required to overcome the adverse effect of cigarette smoking on serum vitamin C levels. Although vitamin C supplementation has been associated with altered protein and amino acid metabolism,[46] increased urinary oxalate excretion leading to calcium oxalate calculi,[47] diminished serum levels of vitamin B12,[48] and interference with urine tests for glucose and stool tests for occult blood,[49,50] these adverse effects have been reported only with daily vitamin C doses of one gram or more. Therefore, increasing the dietary vitamin C intake by an amount sufficient to correct the hypovitaminosis C associated with smoking should be well tolerated. Although the simplest and most direct method to increase the low serum vitamin C levels found in many smokers would be to stop smoking, increasing vitamin C consumption may be appropriate when cigarette cessation is unsuccessful.

Deaths from All Causes in Non-Smokers Who Lived with Smokers

DALE P. SANDLER, PHD, GEORGE W. COMSTOCK, MD, DRPH, KNUD J. HELSING, SCD, AND DAVID L. SHORE, PHD

Abstract: Mortality associated with passive smoking was evaluated in a 12-year study of 27,891 White adult smokers and 19,035 never smokers identified in 1963. Death rates were calculated using an estimate of the person-years at risk. Adjusted for age, marital status, education, and quality of housing, the estimated relative risks of death from all causes were 1.17 (approximate 95% confidence interval 1.01, 1.36) for men and 1.15 (1.06, 1.24) for women with passive exposure. These relative risks were similar to those for ex-smokers and for pipe or cigar smokers. Risks increased slightly with level of exposure. The relative risk from passive smoking was greatest for men under age 50 (RR = 2.09, 1.31–3.34). Risks from passive smoking were slightly elevated for several causes among men and women, and may be broader than those previously reported. On the other hand, these small nonspecific increases in death rates may reflect other characteristics of passive smokers that increase mortality. (*Am J Public Health* 1989; 79:163–167.)

Introduction

Smokers are generally reported to have almost doubled age-adjusted death rates.[1] This increased mortality is observed for all causes combined as well as for specific causes, and is not entirely explained by smokers' substantially increased risk for lung cancer or arteriosclerotic heart disease.

Non-smokers who live with smokers are exposed to many of the same potentially toxic consituents of cigarette smoke[2] and they, too, may be at increased risk for death from a variety of causes. These "passive smokers," like active smokers, have increased levels of smoke by-products in body fluids,[3,4] increased activation of enzyme systems that metabolize potential carcinogens,[5] and increased levels of urinary mutagens,[6,7] albeit all at much lower levels than active smokers.

More than a dozen studies have demonstrated increased lung cancer risk among passive smokers,[2] and several studies have suggested increased heart disease risk for passive smokers.[8–11] Studies have also reported increased overall cancer risk,[12–14] with risks not limited to respiratory tract cancers, but the data are limited and findings inconclusive. Only a few reports have concerned total mortality among passive smokers. In the Multiple Risk Factor Intervention Trial, total mortality was increased nearly two-fold among men at risk for heart disease who were married to smokers.[8] A small increase in total mortality was reported for non-smoking women with environmental tobacco smoke exposure in Scotland, but no association was observed for men.[15] Total mortality was slightly increased for passively exposed women in a small US study,[9] but no association between passive smoke exposure and total mortality was found in a study in Amsterdam.[16]

We evaluated mortality from all causes and specific causes in non-smokers living with smokers who had been surveyed in 1963 as part of a private community-wide census in Western Maryland.

Methods

In July 1963 a private census obtained data on an estimated 98 per cent of the households in Washington County, Maryland. The census provided information on sex, age, race, marital status, years of schooling, church attendance, and housing characteristics for 91,909 individuals. Information on cigarette, cigar, and pipe smoking habits was recorded for each household member age 16-½ or older as of July 15, 1963.

To take into account losses from the population resulting from deaths and emigration, a follow-up study of a 5 per cent sample of households that took part in the 1963 census was conducted in 1971. Age, marital status, years of schooling, and frequency of church attendance were associated with remaining in the county after eight years based on a linear model that adjusted for effects of these and other socioeconomic and demographic variables. The addition of sex, smoking status in 1963, and number of bathrooms to the model did not alter the results. The resulting linear model was used to assign to each adult in the 1963 census their probability of still living in the county. From this, an annual probability could be calculated, allowing the population remaining in the county to be estimated at any point in time. The procedure used to estimate the probability of remaining in the county has been described in greater detail by Comstock and Tonascia.[17]

Death certificates of Washington County residents who died between July 1963 and July 1975 were matched against the census and have been coded by one of the authors (GWC) as to primary, contributing, and underlying causes of death according to the seventh revision of the International Classification of Disease (ICD).[18] For this report, deaths were classified in broad groupings using the underlying cause of death.

Data are reported here for adults who were over age 25 in 1963. Because only about 2 per cent of the census population was Black, the analysis is limited to Whites. This report is based on data from a total of 22,973 White men and 25,369 White women.

Study subjects were classified according to their smoking status in 1963. Smoking status was not known for 587 men (2.6 per cent) and 527 women (2.1 per cent). An additional 212 men and 90 women known to be smokers were excluded from this report because the number of cigarettes smoked was not known, leaving 22,174 men and 24,752 women for analysis.

A household smoke exposure score was calculated to serve as a measure of passive smoking. To create this score, each adult was assigned a smoking contribution score ranging from 0 to 12 based on their personal smoking history.[11] A household smoking total was calculated as the sum of the smoking contribution scores of all persons living in that household, and each individual's household smoke exposure

Current smokers	11,779	2,090	1.41	(1.29, 1.55)	7,716	697	1.26	(1.13, 1.40)
<10 cigarettes	1,583	315	1.14	(0.99, 1.31)	2,248	222	1.12	(0.96, 1.30)
10+ cigarettes	10,196	1,775	1.49	(1.35, 1.64)	5,468	475	1.34	(1.19, 1.52)

Number of subjects
*Adjusted for age, housing quality, schooling, and marital status

score was the household total minus his or her own contribution to it. The person's own smoking was treated separately in the analysis.

The household exposure score cannot measure total passive smoke exposure because it is not known, for example, how many of the cigarettes smoked per day were smoked outside of the home. Nevertheless, this score is an indicator of the relative degree of exposure in 1963. The group of non-smokers living with non-smokers will have had, on average, the least household exposure to tobacco smoke, while persons living with several heavy smokers will have had, on average, the highest levels of household exposure. Among the 4,162 men and 14,873 women who were reported in 1963 as never smokers, 1,248 men (30.0 per cent) and 9,551 women (64.2 per cent) had household smoke exposure and are considered passive smokers; the remainder are considered non-smokers.

A housing index (ranging from 0 to 10) based on running water, number of bathrooms, type of heating system, cooking fuel, and availability of a telephone was created to serve as a rough indicator of quality of housing and socioeconomic status. For this analysis, housing quality has been classified as poor (index = 0–7) or good (index = 8–10). Education has been categorized as 0–8, 9–11, 12, and 13 or more years of schooling. Subjects were characterized as those married in 1963 and those not. In overall analyses, age has been categorized as 25–44, 45–54, 55–64, and 65+. In analyses restricted to those under age 50, age was categorized as less than 40 and 40–49 in 1963. For persons older than 50, age was categorized as 50–59, 60–69, and 70 or more years.

Average annual death rates were calculated as the number of deaths during the 12 years from 1963 to 1975 divided by the number of person-years of follow-up estimated from the assigned probability scores for still living in the county. Relative risks were calculated as the average annual death rates among smokers or passive smokers divided by the death rates among nonsmokers without household smoke exposure. Age, marital status, and other factors were strongly related to both death rates and smoking status in this population. Accordingly, all relative risks were adjusted for differences in age, marital status, housing quality, and education using Poisson regression.[19]

Results

The number of deaths and person years of follow-up are shown by smoking status in 1963 and sex in Table 1. After adjusting for age, marital status, education, and housing quality, passive smokers were at increased risk for death from all causes relative to non-smokers. Adjusted relative risks were 1.17 (approximate 95 per cent confidence intervals 1.01, 1.36) for men and 1.15 (1.06, 1.24) for women. These relative risks were similar to those for pipe or cigar smokers, ex-smokers, and smokers of fewer than 10 cigarettes a day, and were less than half that observed for heavier active smokers.

Among men, the relative risk for passive smokers under age 50 was 2.09 (1.31, 3.34), and the relative risk for heavier active smokers was 3.16 (2.27, 4.41) (Table 2). Among those age 50 and older, the corresponding relative risks were substantially less. The difference between the death rates for passive smokers and non-smokers was similar, however, in both age groups (2.6/1,000 for those younger than age 50 and 2.3 for those 50 and older). Among women, while the relative risk for active smoking was greater for those younger than 50 in 1963, the relative risk for passive smoking did not vary with age. Among passive smokers there was some increase in

overall relative risk for death from all causes with increasing household exposure to smoke, but no clear trends (Table 3).

Passive smoking-associated adjusted relative risks for individual causes of death are shown for never smoking men and women in Table 4. The relative risks for male and female passive smokers were greater than one for several smoking related and other causes, although risk estimates were stable only for arteriosclerotic heart disease in men and for arteriosclerotic heart disease, cerebrovascular disease, and chronic lung disease in women.

There were few deaths among men younger than 50 in 1963, but the relative risks for several causes of death, including arteriosclerotic heart disease and cancer, were greater than 2.00 (data not shown).

The increased relative risk for chronic lung disease among women with smoke exposure was limited to women over age 50 in 1963; there were no deaths in this category among younger women. The risk for cerebrovascular disease did not differ by age, but cancer risk was increased only among women younger than age 50. All 12 "smoking-related" cancers (two lung, five cervix, one kidney, three pancreas) among never smoking women younger than 50 were in those with passive smoke exposure.

Among the never smokers, 44 per cent of the deaths among men and 35 per cent of the deaths among women were attributed to arteriosclerotic heart disease. After excluding these deaths, there continued to be an increase in overall mortality for women with passive smoke exposure (Table 5). For men, mortality from causes other than arteriosclerotic heart disease was increased only among passive smokers younger than age 50 [RR = 1.93 (1.09, 3.41)].

Discussion

The finding of increased overall mortality for non-smokers who lived with smokers may not reflect a causal relationship. Much of the increased risk we observed could be attributed to arteriosclerotic heart disease for which an extensive literature documents an increased risk associated with active cigarette smoking.[20] Our own study[11] and others have demonstrated increased risk for heart disease in passive smokers. Svendsen, *et al.*[8] reported non-smoking men married to smokers were at increased risk for heart disease death [RR = 2.11 (0.69, 6.46)] and risk increased with amount smoked by the spouse. Hirayama[10] reported a 20 per cent increase in mortality from ischemic heart disease among non-smoking women married to smokers. Heart disease

mortality associated with passive smoking was also increased in studies reported by Gillis, *et al.*[15] and by Garland, *et al.*[9] but risk estimates were based on small numbers. A study reported by Lee, *et al.*[21] indicated no heart disease risk from passive smoking.

In our study, an increased relative risk for death remained even after subtracting deaths from arteriosclerotic heart disease. The effect was strongest for women and for younger men. The general increase in mortality leaves open the possibility that the life styles of people who live with smokers differ from those who do not live with smokers. Factors such as alcohol consumption or dietary habits which are correlated with both smoking and risk for some diseases (and which were not collected in the 1963 census) seem especially likely to be alternative explanations for our findings, to the extent that diets or alcohol use are similar among household members.

Studies of passive smokers in general and of passive smokers with heart disease have also examined some of these potential confounding factors with mixed results. In 1963, more than 60 per cent of never smoking women in Washington County lived with smokers,* but it was much less common for non-smoking men to live with smokers. Differences between these men and other men might explain their slight increase in overall mortality. Never smokers who lived with smokers had fewer years of schooling and lived in housing of poorer quality. We adjusted for these differences in our analysis, but residual confounding might still affect our results.

Others have found few differences between those with and without passive smoke exposure that could account for mortality differences between groups. Garland, *et al.*[9] found no difference in blood pressure, obesity, or cholesterol between women married to smokers and those married to never smokers. Svendsen, *et al.*[8] found no differences in blood pressure, cholesterol, or psychosocial factors between men married to smokers and men married to non-smokers. They did, however, find that men married to smokers were slightly heavier and drank alcoholic beverages slightly more often than those married to non-smokers. Similarly, Friedman, *et al.*[22] reported that alcohol consumption and other risk-taking behaviors were more frequent among non-smokers with passive smoke exposure.

Besides heart disease, several other causes of death for which we observed increased death rates for passive smokers are causes that are known or suspected to be caused in part by cigarette smoke. These include respiratory diseases such as emphysema and bronchitis[23] and cerebrovascular disease.[24,25]

Kalandidi, *et al.*[26] recently reported in a case-control study that non-smoking women married to current smokers had nearly twice the risk of lung disease as did non-smoking women married to never smokers. Increased chronic lung disease mortality was also reported by Hirayama[27] for Japanese women married to smokers (RR = 1.4), but results in the study by Lee, *et al.*[21] were inconclusive. Two studies also included data on risk of cerebrovascular disease. Based on very small numbers, stroke risk was increased for women with environmental tobacco smoke exposure in the study by Gillis, *et al.*[15] In the study by Lee, *et al.*[21] stroke mortality was increased approximately two-fold for both men and women with high total passive smoke exposure, although not in relation to spouse smoking alone.

While lifestyle or selection factors are a possible explanation for the small increase in overall mortality we observed, it is also possible that continued exposure to cigarette smoke leads to poorer health in general. Smokers have more respiratory illnesses and decreased lung function relative to non-smokers.[24] They may also have altered immune system responses and other changes which indirectly affect disease risk and response.[1] It is possible that passive smoke exposure indirectly increases overall mortality by altering general health status and increasing case-fatality from other illnesses. Increased respiratory symptoms and decreased lung function have been observed for passively exposed children and adults,[2] although not all studies have been positive.[28]

Finally, with relative risks as low as those observed here, and with such a weak dose-response, one must consider that other biases are responsible for these findings. The confidence intervals for the risk estimates shown do not take into account the variability associated with the estimated person years at risk. These estimates were derived from fitting a linear model to follow-up data obtained for a 5 per cent sample of the population. The true person-years of follow up may be larger or smaller than that calculated. Therefore the reported confidence intervals may be slightly too small.

Misclassification of smoking status is also possible. Smoking status was obtained once in 1963 as part of a general community census. Some persons classified as non-smokers may have taken up smoking in the years between 1963 and 1975, and non-smokers who lived with smokers may be more apt to become smokers. Similarly, non-smokers with no smoke exposure may have become exposed as other family members began to smoke or as household composition changed. However, it is more likely that active smokers became ex-smokers over the 12-year period, reducing the overall level of household smoke exposure at which these effects were observed. Thus the dose-specific effects may even be underestimated. Furthermore, individuals who were not exposed at home may have had smoke exposure at work, making it difficult to detect smoking-related health differences between groups.

NIDA Announces Availability of Videotapes on Drugs in the Workplace

The National Institute on Drug Abuse, the federal agency which serves as the focal point for research and demonstration programs on drug abuse, has announced availability of *Drugs at Work* and *Getting Help*—the first two in a four-part videotape series on drug abuse in the workplace. The videotapes are available either on free loan or for purchase.

- *Drugs At Work*, a 23-minute educational documentary, describes costs of drug use for the workplace, the individual, and the public, and examines action being taken by government and private companies. An important program for all levels in the workplace, from top management to line staff, *Drugs at Work* provides information for developing effective drug abuse workplace programs through policy development, drug testing, employee assistance programs, prevention, and education. Interviews are included with drug users who have sought treatment and with experts on drugs in the workplace. Government and industry representatives describe current federal and corporate programs.
- *Getting Help* presents detailed information about the use of Employee Assistance Programs (EAPs) in addressing drug use in the workplace. The film features comments by business, labor, and government leaders, and EAP professionals; presentation of three model programs; and EAP client interviews. It encourages employers to consider EAPs as a tool in combatting drugs at work, and provides employees with reassuring information about the confidentiality and effectiveness of an EAP program.

The third in the series, *Drug Testing*, and the fourth, *Drug Prevention and Employee Education*, will be available in the near future.

The videotapes—available in both employer and employee versions—are designed to be part of a comprehensive workplace drug abuse program. To arrange a free loan, contact: Modern Talking Picture Service Scheduling Center, 5000 Park Street, North, St. Petersburg, FL 33709, (813) 541-5763. Parental Smoking and Post-Infancy Wheezing in Children: A Prospective Cohort Study

DANIEL R. NEUSPIEL, MD, MPH, DAVID RUSH, MD, NEVILLE R. BUTLER, MD, JEAN GOLDING, MA, PhD, POLLY E. BIJUR, PhD, MPH, AND MATTHEW KURZON, MA, MS

Abstract: The contribution of parental smoking to wheezing in children was studied in a subset of all British births between April 5 and 11, 1970 ($N = 9,670$). Children of smoking mothers had an 18.0 per cent cumulative incidence of post-infancy wheezing through 10 years of age, compared with 16.2 per cent among children of nonsmoking mothers (risk ratio 1.11, 95% CI: 1.02, 1.21). This difference was confined to wheezing attributed to wheezy bronchitis, of which children of smokers had 7.4 per cent, and those of nonsmokers had 5.2 per cent (risk ratio 1.44, 95% CI: 1.24, 1.68). The incidence of wheezy bronchitis increased as mothers smoked more cigarettes. After multiple logistic regression analysis was used to control for paternal smoking, social status, sex, family allergy, crowding, breast-feeding, gas cooking and heating, and bedroom dampness, the association of maternal smoking with childhood wheezy bronchitis persisted. Some of this effect was explained by maternal respiratory symptoms and maternal depression, but not by neonatal problems, the child's allergic symptoms, or paternal respiratory symptoms. There was a 14 per cent increase in childhood wheezy bronchitis when mothers smoked over four cigarettes per day, and a 49 per cent increase when mothers smoked over 14 cigarettes daily. (*Am J Public Health* 1989; 79:168–171.)

Introduction

Children are passive victims of the effects of tobacco smoke from their surrounding environment, resulting in multiple adverse health outcomes.[1–3] Passive smoking has been associated with respiratory infections and symptoms in infants and young children.[4–9] Some studies have suggested an association between parental smoking and wheezing or other respiratory symptoms of older children,[10–14] but other investigations have disputed this relationship.[15–17] A dose effect has been reported,[4,6,12,18–21] although this has been inconsistent and often crudely measured.[8] Parental smoking has also been associated with decreased pulmonary function and lung growth in children.[11,14,19,22–25]

The mechanism of effect of passive smoking on childhood reactive airway disease is not clear. Sidestream tobacco smoke may be directly toxic to the lungs of children. Alternatively, or additionally, the respiratory effects of passive smoking may be mediated by other factors to which children of smokers may be exposed, such as infection,[10,13,26,27] allergy,[15,28] stress,[29] or neonatal respiratory problems.[23]

In order to address some of these unresolved issues, we studied the relationship of cigarette smoking by either or both parents with report of post-infancy wheezing in a large, representative British national cohort.

Methods

The Child Health and Education Study began as a national survey of all births in Great Britain during the week of April 5–11, 1970.[30] Information was collected by midwives during the first postpartum week. At 5 years of age, the cohort was reevaluated by trained health visitors via maternal interviews. Additional parental interviews, medical examinations, and educational evaluations were carried out at age 10.

Maternal smoking behavior was surveyed at each interview, including the duration of smoking from pregnancy through age 10 of the child and the usual dose of cigarettes per day during each period. We asked about the use of cigarettes, pipes, or cigars by the father. The amount smoked by the mother was categorized on the birth questionnaire as 0, 1–4, 5–14, 15–24, and 25 or more cigarettes per day. These categories were applied to doses reported at children's ages 5 and 10, from the continuous measures of amount smoked (there was considerable preference for multiples of five in reporting of dose). In trend analyses, means of each of the first three smoking categories were used: 2.5, 9.5, and 19.5; 29.5 cigarettes per day was used for the highest smoking category.

Outcome data were obtained from maternal interviews when the children were 10 years old. At that time, parents were asked: "Has the child *ever* had one or more attacks or bouts in which there was wheezing or whistling in the chest?" If the reply was positive, they were asked: "What were these thought to be due to?" (. . . asthma, wheezy bronchitis, or other cause, with multiple responses permitted); parents were then asked at what ages the wheezing occurred. Wheezy bronchitis is a common diagnosis in Great Britain, although its clinical distinction from asthma is not clear.

Other variables were selected for study after review of published investigations or parental smoking and other factors related to childhood respiratory symptoms and disease. These included sex of the child, social status of the family (represented by a standardized variable derived from factor analysis of social items when the cohort was 5 years old), crowding in the home (total persons/total rooms), number of siblings (total, older and younger), dampness in the child's bedroom, whether gas was used for cooking and/or heating, child's own smoking at age 10, whether the child was breast fed at least one month, history of allergy in the child or family, neonatal respiratory problems, symptoms of chronic cough or phlegm for over three months in each parent, and a measure of maternal depression (derived from a 24-item Malaise Inventory[31]). Family allergic history was determined at the time the child was age 5 by a report of asthma, eczema, or hay fever in either natural parent. A positive allergic history in the child was defined as a report of eczema or hay

fever before 5 years of age. Neonatal respiratory problems were defined by a history of any breathing difficulties during the first week of life.

Chi-square, multiple logistic regression, and factor analyses were done using SAS software.[32,33] Confidence intervals on risk ratios[34] and on odds ratios determined from multiple logistic regression[35] were calculated using published methods. Attributable risk calculations were done using methods described by Lilienfeld.[36]

Results

We studied prospectively 11,776 children born between April 5–11, 1970 and their families, obtaining data at birth, and at ages 5 and 10 years. Of this population, 9,953 (84.5 per cent) were singleton births, living throughout with their natural mothers, whose primary language was English, and who were ethnic Europeans. In 836 of these households (8.4 per cent), there was no father figure. There were 5,113 boys (51.4 per cent).

The 9,670 children whose mothers had known smoking information comprise the cohort for the remaining analyses. Of these mothers, 4,855 (50.2 per cent) smoked cigarettes at some time between their pregnancy and the child's age 10. Cigarette smoking was reported at some time by 5,128 fathers in homes with a father figure (56.2 per cent). In addition, 866 (9.5 per cent) of fathers smoked pipes or cigars only.

There were 1,774 children (17.8 per cent) who were reported to have wheezed by 10 years of age. Of these, 112 reported wheezing only before one yer of age; the remaining 1,662 were classified by their parents as having asthma, wheezy bronchitis, or other reasons for wheezing. The relationship of post-infancy wheezing to maternal smoking at any time between pregnancy and child's age 10 (dichotomized) is presented in Table 1. Smoking was associated with post-infancy wheezing in the entire group of children (risk ratio 1.11, 95 per cent CI = 1.02, 1.21). This smoking relationship was limited to the subgroup stated to have had wheezy bronchitis (risk ratio 1.44, 95 per cent CI = 1.24, 1.68). Subsequent analyses relate only to this outcome.

Unadjusted relationships of maternal and paternal smoking with child's wheezy bronchitis are shown in Table 2. The effect of maternal smoking was stronger when fathers also smoked, but these mothers also smoked more cigarettes per day: during pregnancy, 12.5 per cent smoked over 14 cigarettes per day, compared with 4.5 per cent when fathers were nonsmokers. In the homes with no father figure, there was a higher cumulative incidence of wheezy bronchitis.

Wheezy bronchitis was reported to have started before age 5 in 72 per cent of affected children (compared with 65 per cent of those with asthma). The amounts that the mother smoked at child's birth and age 5 years were equally strongly related to the risk of wheezy bronchitis. Thus, the mean dose of cigarettes per day between the reported amounts at birth and 5 years was used in subsequent dose analyses. The cumulative incidence of wheezy bronchitis by amount smoked by the mother is presented in Table 3. The incidence of wheezy bronchitis increased progressively from 5.2 per cent in nonsmokers to 8.9 per cent among children whose mothers smoked over 24 cigarettes per day, but this dose-effect trend among smokers was not statistically significant.

Wheezy bronchitis was inconsistently related to the duration and period of maternal smoking (Table 4). Those mothers who smoked throughout the study period (from pregnancy through child's age 10) also smoked more cigarettes; their children had a risk ratio of 1.52 (95 per cent CI = 1.27, 1.82) for wheezy bronchitis compared with nonsmokers. The category of mothers who only smoked in both postnatal periods was most strongly related to childhood wheezy bronchitis, although only 12 cases were exposed in this group.

Multiple logistic regression was used to estimate the effects of several factors of post-infancy wheezy bronchitis contrasted with no history of wheezing. The final model included maternal smoking between child's birth and age 5 years with four dose levels; paternal smoking in three categories: cigarette smoking, pipe or cigar smoking only, or father absent from the home; social status, sex of the child, family history of allergy, crowding, breast-feeding, gas cooking or heating, and bedroom dampness. The included social status items after factor analysis were: father's highest educational qualification, father's occupational social class, mother's highest educational qualification, economic level of the neighborhood, telephone in the home, and ownership/rental of home. Highly correlated, redundant variables (e.g., number of siblings) were substituted by more specific mea-

RR = Risk ratio

sures (e.g., crowding). Variables unrelated to smoking or wheezing were not included.

The interaction between maternal smoking and the following variables were estimated by both bivariate and multivariate analyses: sex, maternal depression, child allergy, parental allergy, neonatal respiratory distress, breast-feeding, gas cooking, gas heating, crowding, social status, or paternal smoking. The effect of maternal smoking on wheezy bronchitis showed little difference among the levels of any of these factors. Thus, the final multiple logistic models excluded interaction terms.

As Table 5 shows, the dose relationship with maternal smoking appeared to plateau at 15–24 cigarettes per day when all potential confounders were controlled. Male sex, low social status, family allergy, and bedroom dampness, when controlled for maternal smoking, were related to wheezy bronchitis.

Several variables were examined as potential mediators of the smoking effects by adding each separately to the full analytic model, including neonatal respiratory problems, child allergy, and parental respiratory symptoms. These mediating effects were strongest among children whose mothers smoked over 24 cigarettes per day: the maternal smoking effect was reduced (from 1.49 to 1.32) when maternal respiratory symptoms were controlled; parental symptoms exerted no such effect, despite the stronger independent contribution of fathers' report of cough or phlegm to the child's symptoms. A smaller reduction in effect (to 1.36) was evident when maternal depression was included in the analysis. An increase in the effect (to 1.61) was seen when child allergy was held constant. Neonatal respiratory problems showed no mediating effect.

If mothers smoking over four cigarettes per day had not smoked, we estimate that 13.8 per cent of the total burden of wheezy bronchitis in this population would not have occurred.

Social status factor	0.90 (.81, .99)

Discussion

In this large, representative national cohort of British children followed from birth, 18 per cent were reported to wheeze by 10 years of age. A subgroup of these children (those whose symptoms were attributed by their mothers to wheezy bronchitis) were at increased risk of post-infancy wheezing when their mothers were smokers. Paternal smoking did not contribute independently to the risk of wheezy bronchitis, perhaps because young children spent more time with their mothers. Recent changes in parental work and child care patterns may alter these relationships.

Is tobacco smoke directly toxic to children's lungs, or are its effects attributable to other factors? Parents who smoke have more respiratory symptoms themselves and may transmit infections to their children.[10,26,27] Additionally, children may imitate the respiratory symptoms of their parents. We found that report of maternal cough or phlegm resulted in some attenuation of the relationship of maternal smoking with the child's wheezy bronchitis; paternal symptoms showed no such relationship. This finding is consistent with mediation of some of the effect of maternal smoking on the child's wheezing by maternal respiratory symptoms; it also is consistent with maternal smoking jointly causing maternal symptoms and the child's wheezy bronchitis, or with more frequent reports of wheezy bronchitis in children of smoking mothers with respiratory symptoms. A substantial portion of childhood wheezy bronchitis was unexplained by these mediating factors, either due to actual toxicity of sidestream tobacco smoke or unexamined mediating factors.

Passive smoking was related only to wheezy bronchitis and not to reported asthma or wheezing for other reasons. We do not know what clinical characteristics led to the perceived diagnosis of wheezy bronchitis in these children. Several investigators have suggested that asthma and wheezy bronchitis are clinically and pathologically indistinguishable, and that they are both manifestations of reactive airway disease.[37,38] The distinct patterns of association of different categories of wheezing with parental smoking found in this cohort may represent true differences between various forms of wheezing.[39] Alternatively, children exposed to tobacco smoke may have been labeled disproportionately as having wheezy bronchitis by health care providers because of earlier age of onset than expected for asthma, relative absence of other atopic symptoms, or awareness of early published reports of an association between passive smoking and bronchitis in childhood.

Reliance on parent report of smoking and retrospective report of childhood wheezing may add uncertainty to our findings.[8,24] However, the causal relationship between pas-

sive smoking and childhood reactive airway disease is supported here by consistency with previous investigations, temporal coherence of the sequence of exposure and symptoms, a dose-response gradient, and biologic plausibility.[40] Our data do not reveal a specific period of vulnerability to the effects of passive smoking. Further follow-up of this cohort is in progress and may add to our understanding of the effects of passive and active smoking on the natural history of reactive airway disease.

We estimate a 49 per cent increase in the prevalence of childhood wheezy bronchitis by age 10 when mothers smoke more than 14 cigarettes per day, when compared with children of nonsmoking mothers. Perhaps as much as 14 per cent of wheezy bronchitis in this population can be attributed to maternal smoking of over four cigarettes per day. These findings add evidence of the public health hazards of cigarette smoke to those involuntarily exposed.

Nicotine Intake in Young Smokers: Longitudinal Study of Saliva Cotinine Concentrations

ANN D. MCNEILL, BSC, MARTIN J. JARVIS, BSC, MPHIL, JOHN A. STAPLETON, MSC, ROBERT J. WEST, BSC, PHD, AND ANDREW BRYANT, LRSC

Abstract: Smoking habits and smoke intake were studied over three consecutive years in 197 girls, initially aged 11 to 14 years. Saliva cotinine concentrations in girls who were smokers throughout the three years increased over each year of the study, the greatest increase occurring during movement from occasional to daily smoking. Cigarette consumption also increased over the two years. For a group of continuing daily smokers (n = 23), inhalation of smoke per cigarette as indexed by the ratio of cotinine concentration to average daily cigarette consumption did not change over time. Cotinine concentrations in 16 girls who were smoking on a daily basis within a year of starting to smoke suggested the early development of inhalation. Our findings suggest that young smokers learn to inhale cigarette smoke very early in their smoking careers, that further increases in smoke intake mainly reflect increased cigarette consumption, and that the pharmacological effects of nicotine are already important in reinforcing their smoking. (*Am J Public Health* 1989; 79:172–175.)

Introduction

Nicotine is known to play an important role in smoking addiction in adults,[1] but has been little studied in the early stages of smoking in children.

Questionnaire measures such as cigarette consumption give only a rough estimate of nicotine intake[2] and need to be supplemented by biochemical measures. Nicotine has a relatively short half-life (approximately two hours) in the body so that its plasma concentration is primarily a measure of the last few cigarettes smoked.[3] Cotinine, a major metabolite of nicotine, has a longer half-life (approximately 16 hours[4]) and its concentration in plasma and saliva has been used as a marker of nicotine intake in adults.[3] Quantitative estimation of smoke intake in the early stages of smoking requires objective measures which are sensitive even to intermittent smoking, and it has recently been shown that saliva cotinine provides such a measure.[5,6]

Analysis of cross-sectional data has suggested an early development of smoke intake in young smokers. Inhalation as reflected in cotinine concentrations and expired air-carbon monoxide values was already established in teenage smokers and showed little tendency to increase with age,[5,7] suggesting that smoke inhalation may not increase with the number of years of smoking.

This paper reports on a longitudinal study of smoking which included measurement of saliva cotinine and was carried out over three consecutive years from 1985 to 1987 among the pupils attending a girls' comprehensive school in inner London. The study focuses on girls who were smoking at the outset or who took up smoking during the course of the study. Cross-sectional results for the whole school in 1985 have been reported elsewhere.[5,7]

Method

Smoking surveys were scheduled as a curriculum activity for each class between January and March in 1985, 1986, and 1987. Testing was carried out usually in the late morning or early afternoon, and one further attempt was made to test those who had been absent. The pupils did not know in advance that they would be tested, although they were aware that the program was under way. On each occasion, the girls completed a smoking questionnaire and provided saliva samples for cotinine analysis. Before filling in the questionnaires, they were told that the biochemical measure could detect smoking.

Saliva was collected using cotton dental rolls which were placed in the mouth between cheek and gum during the 20 minutes it took to complete the questionnaires. The saliva was subsequently extracted and frozen until analysis for cotinine by gas chromatography.[8]

Repeated measures analyses of variance were carried out using the SPSSX Manova routine to investigate trends over time in cotinine concentrations and cigarette consumption.

Results

Three hundred seventy-four girls (91 per cent of the number on roll in the first, second, or third years) were present and surveyed in 1985. Their ages ranged from 11 to 14 years (mean 13.0, SD=0.8). A cohort of 197 girls (53 per cent of those surveyed in 1985, 60 per cent of those still at the school) had complete data at all three points of the survey (Table 1).

The smoking prevalence (defined as any current smoking) of this cohort increased from 28 per cent in 1985 to 36 per cent in 1987 (Figure 1). Of the 54 self-reported smokers in 1985, seven reported having quit by 1987. Of those smoking in 1985, there were 27 (50 per cent) daily smokers of whom only one had quit by 1987.

Continuing Smokers

Forty-three girls were self-reported smokers on all three occasions. Their cotinine concentrations increased linearly over time (a mean increase of 52.4 ng/ml per year, Table 2). There was no evidence of a quadratic trend, indicating no slowing down of the increase in the second year.

Eighteen (42 per cent) of these 43 smokers classified themselves as occasional smokers in 1985. By 1986, 12 (67 per cent) of these had progressed to daily smoking and were still daily smokers in 1987 (subsample 1, Table 2). Within this

TABLE 1—Number (%) of Adolescent Girls Eligible for Follow-up Participating in Each of Three Surveys

	1985	1986	1987	Follow-up Cohort
No. (%) present and surveyed	374 (100)	300 (80)[a]	278 (74)	250[b] (67)
No. (%) with complete questionnaire and cotinine data	322 (86)	285 (76)	259 (69)	197[c] (53)

a) Percentages are of those girls present and surveyed in 1985.
b) Losses to follow-up were due to illness or truancy (n = 76) or having moved to another school (n = 48).
c) Missing data were due to incomplete questionnaires (n = 6), refusal to give saliva (n = 1), and those saliva samples discarded due to contamination or insufficient volumes obtained (n = 46). The latter were divided equally between self-reported smokers and non-smokers, the majority (n = 30) occurring in 1985 due to the dental rolls being soaked for an inadequate length of time. Ensuring that they were kept in the mouth for a minimum of 20 minutes largely removed this problem in the later surveys.

group there was a clear linear trend in cotinine concentrations and a suggestion of a quadratic effect, the latter indicating that the increase was greater during the first year of the study when they moved from occasional to daily smoking.

Within a group of 23 girls who were self-reported daily smokers on all three occasions (subsample 2, Table 2) cotinine concentrations showed no quadratic change but increased linearly over the course of the study.

Substantial differences were apparent in the changes in cotinine concentrations between these two subsamples from 1985 to 1986 (difference = 79.9; 95 per cent CI = 7.5,152.3) but not from 1986 to 1987 (difference = 13.0; 95 per cent CI = −54.7,80.7) by which time both groups were smoking on a daily basis.

Usual weekly cigarette consumption increased linearly over time for all smokers. For the subsample of 1985 occasional smokers who were daily smokers in 1986 and 1987, a quadratic trend was also apparent (Table 2).

A question of interest is whether there was any change in smoke intake per cigarette over the two years. A direct measure of this was not taken but it can be indexed approximately by the ratio of cotinine concentration to usual daily cigarette consumption. A repeated measures analysis of variance indicated no change in this index over time for the 23 continuing daily smokers (data available on request to authors). For occasional smokers, the infrequent nature of their smoking, and the ambiguity arising from passive smoking cotinine levels, would make a similar analysis unreliable.

Girls Taking up Smoking During the Study

Thirty-five (25 per cent) of the 1985 non-smokers took up smoking over the following two years (23 in 1986, 12 in 1987). Their mean cotinine concentration after less than one year of smoking was 57.2 ng/ml (SD = 85.1) and their mean weekly cigarette consumption 24.1 (SD = 69.9). Sixteen (64 per cent) of these girls had taken up *daily* smoking within a year and had an end of year mean cotinine concentration of 87.8 ng/ml (SD = 92.8) and daily cigarette consumption of 4.6 (SD = 3.9).

Of the 23 girls who had taken up smoking in 1986, 12 (52 per cent) were still smoking one year later; their cotinine concentrations increased substantially over the next year (Table 2). Nine (75 per cent) of these girls were smoking on a daily basis by 1987.

Discussion

To our knowledge, the stability of cotinine or nicotine concentrations over a period of years has not yet been determined in adults. However, it is known that steady-state blood nicotine concentrations are maintained from one day to the next[10] and this stability would probably remain over a longer period of time. Two recent surveys of adult smokers give average saliva cotinine concentrations of 350 ng/ml for cigarette consumption averaging 25 cigarettes a day.[11,12] This stability contrasts with the situation found in this group of

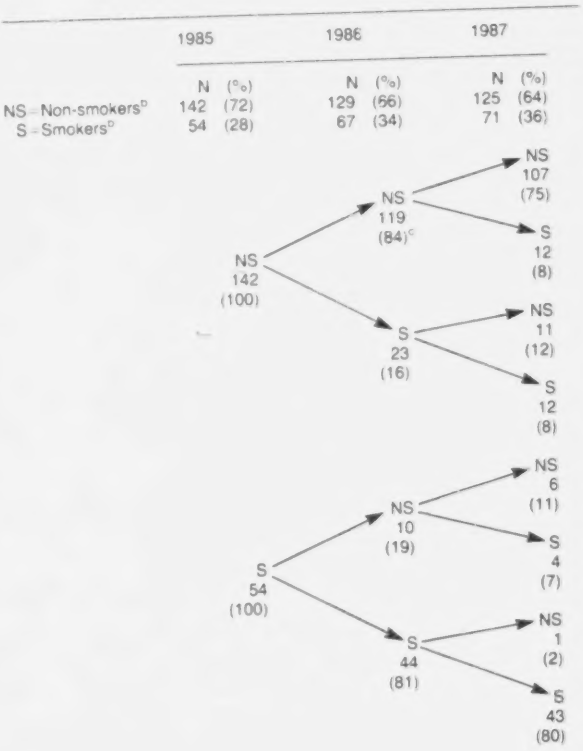

FIGURE 1—Smoking Behavior of the Follow-up Cohort (n=196[a])

a) One self-reported non-smoker in 1985 had a cotinine concentration above a smoking/non-smoking cut-off[4] and was excluded from further analyses.

b) The measure of smoking behavior was a version of Bewley's[9] scale: 1="I have never smoked a cigarette, not even a puff"; 2="I have only ever tried smoking once or twice"; 3="I used to smoke sometimes but I don't now"; 4="I smoke sometimes but don't smoke as much as 1 cigarette a week"; 5="I usually smoke between 1 and 6 cigarettes a week"; 6="I usually smoke more than 6 cigarettes a week." Non-smokers were defined as those who classified themselves in categories 1 to 3, smokers in categories 4 to 6.

(c) Percentages (in parentheses) are of 1985 Non-smokers or Smokers.

TABLE 2—Mean (SD) Cotinine Concentrations and Cigarette Consumption Measures for Continuing Smokers and New Smokers.

				Trend Coefficients (95% CI)	
	1985	1986	1987	Linear Component	Quadratic Component
Smokers at all Three Points of the Survey (n=43)					
Cotinine concentrations	103.6 (89.9)	158.7 (109.7)	208.5 (120.3)	52.4 (35.6,69.2)	−2.7 (−28.9,23.5)
Weekly cigarette consumption	30.9 (44.9)	39.3 (30.7)	55.7 (36.9)	14.4[b] (8.2,20.2)	4.1 (−2.9,11.1)
Subsample 1: 1985 Occasional[c] Smokers, Daily in 1986 and 1987 (n=12)[d]					
Cotinine concentrations	35.7 (49.1)	157.4 (101.7)	206.7 (146.8)	85.5 (42.3,128.7)	−24.3[b] (−62.1,3.8)
Weekly cigarette consumption	2.3 (1.5)	32.5 (18.3)	40.2 (21.0)	19.0 (12.2,25.7)	−11.3 (−21.0,−1.6)
Subsample 2: Daily Smokers in all Three Years (n=23)[e]					
Cotinine concentrations	159.5 (78.6)	201.4 (99.2)	237.7 (94.0)	39.1 (23.8,54.4)	−2.8 (−42.5,37.0)
Daily cigarette consumption	7.6 (7.4)	9.7 (6.0)	11.2 (4.7)	2.2[b] (1.3,3.0)	−0.3[b] (−1.0,1.4)
Non-smokers in 1985, Smokers in 1986 and 1987 (n=12)					
Cotinine concentrations	5.3 (3.7)	57.9 (75.6)	149.4 (111.1)	91.5 (12.7,170.2)	
Weekly cigarette consumption	—	14.3 (18.5)	50.5 (39.8)	36.3 (14.7,57.8)	

a) Weekly cigarette consumption was defined by the following questions: "How many cigarettes have you smoked in the last week" (1986); "How many cigarettes have you smoked in the last seven days" (1987). The 1985 measure was derived from self-reported daily cigarette consumption and the smoking status question from that year.[5]

b) Due to a skewed distribution in these components, log transformations were used.

c) Daily and occasional smokers were differentiated by the question: "If you smoke, do you usually smoke every day?"

d) Of the remaining eight smokers, six occasional smokers continued to smoke on an occasional basis in 1986 (of whom four had taken up daily smoking by 1987) and two of the daily smokers reverted to occasional smoking during the course of the study (one of whom had resumed daily smoking by 1987).

e) This measure was only available for the self-reported daily smokers.

adolescent girls where cotinine concentrations increased substantially over time. Although the greatest rise in cotinine concentrations occurred during movement from occasional to daily smoking, smoke intake continued to increase albeit less rapidly, on attaining a regular daily smoking pattern. Cotinine concentrations even at the beginning of the study were substantial, with approximately half the average adult concentration being observed in the 11 to 14 year old daily smokers. Two years later the same group had levels more than two-thirds those in the adult surveys. This is in spite of the fact that these young smokers were at school and subject to considerable restrictions on their smoking behavior and probable financial limitations on the number of cigarettes they could smoke.

Hence, these girls were receiving substantial doses of nicotine from a very early stage in their smoking careers. This suggests that pharmacological effects of nicotine were already important in perpetuating their smoking. Other analyses of the 1985 data indicate an early development of pharmacological addiction: young smokers reported experiencing calming effects when smoking and withdrawal effects during attempts to give up which were similar to those experienced by adult smokers.[13,14]

Since cigarette consumption in our sample also increased over the two years, it seems likely that the increase in cotinine concentrations in our sample was due in part to an increase in cigarette consumption. Indeed, an index of smoke intake per cigarette computed for the continuing daily smokers showed no tendency to increase over the two years. An early development of inhalation is also suggested when examining the cotinine concentrations for the 16 adolescents who had been smoking for less than one year yet were already daily smokers. Nevertheless, changes in nicotine metabolism, cotinine half-life or simply a lack of precision in the cigarette consumption measures in this sample of adolescents could disguise the true picture and growing adolescents would have to increase their smoke intake over time to counteract any concomitant increases in body weight. Therefore, we cannot rule out the possibility of increases in the amount of smoke inhaled per cigarette during these years.

Although this sample was made up entirely of girls, there is no *a priori* reason to expect the findings would not also apply to boys. Attrition of the follow-up cohort due to sickness, truancy and leaving the school may mean that there was some selection bias in our sample. It is also possible that the study itself may have influenced smoking behavior. However, the likely direction of such effects would mean that our findings would be conservative.

Our results indicate that nicotine is already important in maintaining the smoking habit in adolescents. Obviously, interventions are needed well before this stage is reached and preferably before the onset of smoking, which in many cases would appear to be before arrival at secondary school.[15]

ACKNOWLEDGMENTS

We would like to to thank all the pupils and teachers at the school concerned for their cooperation, and our colleagues at the Addiction Research Unit for their helpful comments on an earlier draft of this paper. We are grateful to the Medical Research Council for financial support.

Surgeon General C. Everett Koop Receives APHA Award for Excellence

Editor's Note: At its 116th annual meeting in Boston, November 13–17, 1988, the American Public Health Association conferred its 1988 Award for Excellence on C. Everett Koop, MD, United States Surgeon General, in recognition of his "exceptional contributions to the improvement of the health of the people." During an Honors Assembly held November 14, the Association recognized the "meritorious contributions" made by Dr. Koop during his seven years as Surgeon General. Portions of the citation read in honor of Dr. Koop dealt particularly with his leadership role in relation to the tobacco issue. This issue of the Journal focuses on the subject of tobacco, smoking, and smoking cessation in honor of the 25th anniversary of the Surgeon General's first report on smoking and health. Excerpts from the citation honoring Dr. Koop last November are printed below:

Excerpts from APHA Citation for Surgeon General Koop

". . . .Dr. Koop has maximized the symbolic authority of the Surgeon General's office . . . Through a fortuitous conjunction of his own substantial leadership qualities with the extraordinary health challenges of our day has come a dramatic and lasting impact upon our society and the health of our people. . . .

"As the nation's most recognized spokesperson for public health, he has used the high visibility of his office with great effectiveness to mold public opinion and to stimulate societal action for the prevention of disease and the promotion of health, focusing particularly upon two of the most pressing health issues of our day—tobacco and AIDS. It is especially for these achievements we cite Surgeon General Koop.

"Soon after becoming Surgeon General, he surprised some by continuing to speak out forcefully and frequently concerning the adverse health effects of smoking. He became the first federal official to speak out explicitly and authoritatively for a 'smoke-free society.' With increasing public attention, he personally promoted the now traditional annual Surgeon General's reports on smoking and health. In one, he openly documented the compelling evidence against passive smoking. In another, he boldly and soundly exposed the addictive nature of tobacco. Yet another targeted the expanding consequences of smoking on women's ill health. He unabashedly assaulted the commercialization of disease and death by the tobacco industry, and endorsed the desirability of a ban on the advertising of tobacco products.

. . .

"The American Public Health Association is pleased to present its 1988 Award for Excellence to Surgeon General C. Everett Koop in recognition of his exceptional contributions to the improvement of the health of the people."

A Survey of Smoking and Quitting Patterns among Black Americans

Carole Tracy Orleans, PhD, Victor J. Schoenbach, PhD, Mary Anne Salmon, PhD, Victor J. Strecher, PhD, William Kalsbeek, PhD, Dana Quade, PhD, Edward F. Brooks, DrPH, T. Robert Konrad, PhD, Charles Blackmon, MBA, and Charles D. Watts, MD

Abstract: A sample of adult Black policyholders of the nation's largest Black-owned life insurance company was surveyed in 1986 to add to limited data on smoking and quitting patterns among Black Americans, and to provide direction for cessation initiatives targeted to Black smokers. Forty per cent of 2,958 age-eligible policyholders for whom current addresses were available returned a completed questionnaire. Population estimates for smoking status agree closely with national estimates for Blacks age 21–60 years: 50 per cent never-smokers; 36 per cent current smokers; 14 per cent ex-smokers. Current and ex-smokers reported a modal low-rate/high nicotine menthol smoking pattern. Current smokers reported a mean of 3.8 serious quit attempts, a strong desire and intention to quit smoking, and limited past use of effective quit smoking treatments and self-help resources. Correlates of motivation to quit smoking were similar to those found among smokers in the general population, including smoking-related illnesses and medical advice to quit smoking, previous quit attempts, beliefs in smoking-related health harms/quitting benefits, and expected social support for quitting. Methodological limitations and implications for the design of needed Black-focused quit smoking initiatives are discussed. (*Am J Public Health* 1989; 79:176–181.)

Introduction

Promoting smoking cessation among Black Americans has been declared a public health priority.[1] Blacks, who account for 12 per cent of the US population, constitute the nation's largest minority group and have the highest smoking rate: 34.8 per cent of all Black Americans smoke compared to 29.7 per cent of non-Hispanic White and 25.7 per cent of Hispanic adults.[2] Among Black Americans, as for the US population as a whole, smoking rates are highest, and quit rates are lowest, within lower income and blue-collar subgroups.[3,4] Blacks also suffer the nation's highest rates of mortality and morbidity from smoking-related cardiovascular diseases and cancer—including coronary heart disease and lung cancer.[4–6] Moreover, smoking compounds other serious health risks within the US Black population, including a disproportionate incidence of infant mortality and low birthweight, hypertension, and diabetes.[6]

To date, relatively little research has been done to clarify smoking and quitting patterns and determinants among Black Americans, or to test quit smoking treatments in Black populations.[3,7,8] This paper presents results of a survey on the smoking and quitting patterns of lower and lower-middle income Black Americans. The survey was conducted to aid in the design of needed Black-focused quit smoking initiatives and to prepare for a smoking cessation intervention trial among policyholders of the North Carolina Mutual Life Insurance Company, the nation's largest Black-owned life insurance company.

Methods

Study Population

The target population for the survey consisted of North Carolina Mutual (NCM) Life Insurance Company policyholders aged 21–60 with active individual life insurance policies as of December 1985 and residing in 12 Southern, Mid-Atlantic, and Midwestern states and the District of Columbia where the company maintains active sales offices. All individual policyholders are Black and from predominantly low and lower-middle income groups. A stratified simple random sample for 4,000 NCM policyholders aged 20–61 was drawn from an unduplicated computer file of approximately 178,000 holders of individual life insurance policies in 37 geographic sales districts. To improve the statistical quality of survey estimates, selection of the sample was stratified by sex, age, and whether or not the policyholder had an industrial-type policy. Industrial policies (69 per cent of policyholders) have weekly or monthly agent collection of premium payments ("home service") and face values mostly under $1,000; ordinary policies are of either "home service" or mailed premium types and have face values of at least $1,000. Males were slightly oversampled to achieve a more nearly sex-balanced sample than the original policyholder sampling frame (57 per cent female).

Data Collection

The survey was conducted from April-September 1986. A variety of organizational factors and research objectives dictated the design of data collection procedures. At the time of the survey, the NCM home office did not maintain current addresses or telephone numbers for industrial policies. Its approximately 500 field agents, who see most policyholders on a regular basis, were regarded as the key to obtaining access to and cooperation of policyholders. Furthermore, since agents were to play a major role in a smoking cessation trial to follow this survey, involving them in data collection was essential to building a collaborative research relationship and assessing their research capabilities.

Agents were asked to:

- supply up-to-date mailing addresses and telephone numbers for all of their policyholders selected into the sample;
- notify subjects about the survey before mailing the survey questionnaires or deliver them in person;
- make a follow-up call or visit several days later to encourage cooperation and answer questions; and
- visit nonrespondents in person to provide further encouragement or assistance if needed.

District-based group training sessions instructed agents in how to introduce the survey and encourage participation, and included both videotaped modeling of agent contacts and printed guidelines emphasizing confidentiality of responses. To minimize policyholder concerns about confidentiality, a cover letter attached to the survey explained the purpose of the study with assurances that participants would be identified only by code number, that completed surveys would be delivered in a sealed envelope to the research team at the University of North Carolina, and that individual results would neither be reported to NCM nor ever affect insurance rates or coverage. Cooperation was encouraged through modest lottery-style financial incentives for agents and policyholders, with primary reliance for agent compliance on the company's management structure. For reasons of policyholder and agent relations, NCM management discouraged direct contact with nonrespondents.

The "Smoking and Health Survey" requested sociodemographic information from all respondents (one page) and included separate additional sections for smokers (four pages) and ex-smokers (three pages).* Current smokers were asked about smoking rate, brand (brand name and Uniform Product Code number), nicotine dependence,[10] past attempts to quit or cut down, current desire to quit, beliefs about smoking health harms and quitting benefits, presence of smoking-related illnesses, and interest in self-help materials. Ex-smokers were asked about past smoking and quitting history and reasons for quitting. Standard smoking history items from the National Cancer Institute's self-help smoking cessation trials were used whenever possible.[11] The questionnaire was carefully pilot-tested for readability and ease of completion.

Results

Agents provided usable mailing addresses for 2,958 sample policyholders and reported an additional 249 as having lapsed policies. Withdrawing these 249 inactive policyholders, 107 potential subjects in a district selected for pretesting and 25 served by district offices no longer active yielded a potential sample of 3,619 subjects. Completed surveys were received from 1,237. Eliminating 74 respondents (6 per cent) ineligible on the basis of age left 1,163 eligible respondents. Counting as nonrespondents both those for whom agents did not supply an address and those who failed to return a completed questionnaire yields a 32 per cent response rate (1,163/3,619). Restricting the denominator to policyholders for whom agents supplied mailing addresses and correcting for estimated age-eligibility yields a 40 per cent participation rate (1,163/2,884).

Response rates for the 35 study sales districts ranged from 7 per cent to 62 per cent (median 38 per cent). Although there were regional patterns (generally higher rates in the South [15–62 per cent] and lower rates in the Midwest [10–51 per cent] and Mid-Atlantic [7–47 per cent]), there were marked differences within the same state or even the same city. Apparently valid addresses were obtained for 80 per cent or more of subjects in 25 (71 per cent) of the districts; seven districts provided addresses for only 45–69 per cent of subjects. Differences in district response rates appeared to be due to differences in access to policyholder populations and in agent and management enthusiasm for the survey. No relationships between response rates (as a percentage of the sample or as a percentage of apparently valid addresses) and prevalence of smokers, ex-smokers, and never-smokers were apparent in scatter plots.

Characteristics of respondents were compared with those of the total eligible sample in order to identify any systematic nonresponse patterns. Among the 16 sampling strata formed by sex, age, and type of policyholder, response rates varied from 22 per cent to 43 per cent. Response rates were 26 per cent (about 10 percentage points) lower for industrial policyholders, due to the unavailability of 26 per cent of their addresses. Rates for males were 11 per cent (4 percentage points) lower than for females, in both industrial and ordinary categories. Industrial policyholders, males, and industrial male policyholders age 40 years and younger were slightly underrepresented in the (unweighted) respondent sample (63 per cent vs 69 per cent, 46 per cent vs 49 per cent, 15 per cent vs 20 per cent, respectively, for respondents vs eligible sample).

To help compensate for nonresponse bias and to correct for the disproportion resulting from intentional oversampling of males, all estimates presented in this paper were weighted to the age, sex, and policy type distribution of the policyholder population. This was accomplished by means of a standard adjustment whereby, in effect, the mean of similar respondents was used as a proxy for each nonrespondent.[12] Estimates and variances were calculated using a computer program designed to properly account for the complexity of the sampling design.[13]

Smoking Status and Sociodemographic Data

Based on data from the 1,163 respondents, it was estimated that 50 per cent of NCM's policyholders were never-smokers, 36 per cent were current smokers, and 14 per cent were ex-smokers (see Table 1). The majority of policyholders were women, with a mean age of 39 years. Fewer than half were married. Most had a high school education or less, and most were employed full-time. Respondents reported a mean of 2.5 ambulatory medical visits in the past year, and 84 per cent described their health as "good" or "excellent."

Two-sample t-tests (two-tailed) and chi-squares showed expected relationships of smoking status to age, sex, marital status, education, employment and health.** Never smokers were predominantly women. Ex-smokers were older than current or never smokers. Fewer current smokers than ex-smokers or never smokers were married, employed full-time, or in excellent/good health. Both current smokers and ex-smokers were less likely to have completed high school than never smokers. One-third of current smokers, but half of ex-smokers, reported above normal weight for height and sex, and the mean Quetelet (weight/height) index was significantly higher for ex-smokers than for current smokers.[14]

Current Smokers' Smoking and Quitting Patterns

Current smokers began smoking at a mean of 17.5 years and had smoked for a mean of 19.4 years (Table 2). They were predominantly low-rate smokers, reporting an average of 14

*A detailed report of data collection and agent training methods and a copy of the survey instrument can be obtained from Mary Anne Salmon, PhD, Health Services Research Center, University of North Carolina, Chapel Hill, NC 27599-7490.

TABLE 1—Sociodemographic Characteristics of Individual North Carolina Mutual Policyholders by Smoking Status, 1986

Characteristics	Current Smokers (N = 399)	Ex-Smokers (N = 175)	Never Smokers (N = 589)	Total (N = 1163)
% Smoking Status	35.8 (1.7)	14.2 (1.2)	49.9 (1.7)	100.0
Mean age	37.2 (0.6)	45.1 (1.0)	38.5 (0.5)	39.0 (0.3)
% Female	49.5 (2.7)	47.4 (4.2)	69.8 (1.9)	59.3 (0.6)
Education				
% < High School	32.8 (2.8)	33.8 (4.1)	20.1 (1.8)	26.5 (1.5)
% High School	40.7 (3.1)	30.5 (4.3)	36.4 (2.3)	37.1 (1.7)
% > High School	26.5 (2.7)	35.7 (4.3)	43.5 (2.4)	36.4 (1.7)
Employment				
% Employed Full-time	49.8 (3.1)	69.4 (4.0)	65.9 (2.3)	60.6 (1.7)
% Married	27.8 (2.6)	52.0 (4.5)	43.2 (2.4)	38.9 (1.6)
Health Status				
% Excellent Good	77.5 (2.6)	84.5 (3.7)	88.7 (1.6)	84.2 (1.3)
% Fair Poor	22.5 (2.6)	15.5 (3.7)	11.3 (1.6)	15.8 (1.3)
Mean medical visits past year	2.4 (0.2)	3.0 (0.3)	2.4 (0.3)	2.5 (1.7)
Relative weight of smokers and ex-smokers				
% Normal or Low	66.7 (2.8)	49.0 (4.5)		
% Moderate Overweight	10.3 (1.8)	13.4 (2.8)		
% Severe Overweight	23.1 (2.6)	37.6 (4.4)		
Mean Quetelet Index	29.5 (0.5)	32.1 (1.1)		

Estimates are weighted to compensate for stratification and nonresponse. Standard errors are given in parentheses. No variable missing in >10 per cent of cases.

cigarettes a day. Fifty-two per cent smoked 10 or fewer cigarettes a day, and only 12 per cent smoked 21 or more cigarettes a day. However, most smoked high nicotine brands and most smoked within 30 minutes after waking, a crude index of high nicotine dependency.[10] Almost three-fourths smoked menthol brands; three menthol brands that dominate among Black smokers[15] (Kool, Newport, and Salem) accounted for 55 per cent of brands reported. Only 11 per cent of current smokers used tobacco products other than cigarettes.

Smokers in this population were estimated to have a mean of 3.8 lifetime quit attempts, relying mainly on self-change strategies and will power. Almost 80 per cent had tried once or more to quit, but fewer than 5 per cent had ever tried a formal group or individual treatment. Likewise, more had tried ineffective drugstore aids (14 per cent) than either self-quitting guides (9 per cent) or nicotine gum (7 per cent).

About nine in 10 current smokers had cut down their smoking in one or more ways during the past year. Cutting down on the number of cigarettes smoked and cutting down on smoking around nonsmokers were more common than either inhaling less of each cigarette or switching to lower nicotine brands.

Approximately one-fourth of current smokers had suffered from a smoking-related chronic illness in the past year (hypertension, heart disease, diabetes, bronchitis, emphysema, asthma and/or lung cancer), and over one-third had received personal medical advice to quit in the past year. Smokers generally expressed a moderately strong desire to quit smoking and strong beliefs in smoking health harms and quitting benefits, but they expected only moderate social support for their quitting efforts. Two-thirds were "seriously thinking about quitting smoking in the next year," placing them in the "contemplation stage" as defined by Prochaska and DiClemente.[16] Nine in 10 current smokers were interested in receiving a free self-quitting guide from NCM; 64 per cent were "very" interested.

To identify correlates of strong quitting motivation, the 47 per cent of current smokers with maximum "desire to quit" ratings on an 11-point scale were compared with the remaining 53 per cent on sociodemographic and smoking history variables. As Table 3 shows, the following variables were significantly associated with a strong desire to quit: female gender; lower nicotine cigarette brand; greater number of cut down strategies and previous quit attempts and methods; smoking-related illness or medical advice to quit smoking in the past year; stronger beliefs in smoking health harms and quitting benefits; and greater social support expected for quitting.

Ex-Smokers' Smoking and Quitting Patterns

Ex-smokers and current smokers were similar in regard to mean age of smoking onset (18 years) and mean smoking history (17.5 years) (see Table 2). Ex-smokers were older than current smokers and had been off cigarettes for an average of 10 years; only 9 per cent presently used other tobacco products. Like current smokers, ex-smokers had a relatively low daily smoking rate before quitting (15.5 cigarettes/day). Fewer ex-smokers than current smokers had routinely smoked within 30 minutes after waking.

As shown in Table 4, ex-smokers cited health concerns as foremost reasons for quitting: the desire to overcome present smoking-related symptoms was most often noted, followed by the desire to avoid future illness. Self-mastery motivation and quitting to set a better example for children or others were the next most common reasons. A variety of other motivations—economic, religious, cosmetic, social—were also endorsed.

We also asked ex-smokers to recall the quitting and cut down methods they tried (Table 2). Fewer ex-smokers than current smokers reported cut-down strategies: this difference was most pronounced for "cutting down around others who did not smoke," likely reflecting the major shift over the past decade in smoking norms and in knowledge and attitudes about second-hand smoke. Comparably small proportions of ex-smokers and current smokers had used formal treatments.

TABLE 2—Smoking and Quitting History for Current and Ex-Smokers

Variables	Current Smokers (N = 399)	Ex-Smokers (N = 175)
Mean age started smoking	17.5 (0.3)	18.1 (0.3)
Mean age quit (ex-smokers only)		35.5 (0.8)
Mean years quit (ex-smokers only)		9.5 (0.8)
Mean years smoked	19.4 (0.6)	17.5 (1.1)
Mean cigarettes per day	13.9 (0.6)	15.5 (1.1)
% smoking		
≤10 cigarettes day	51.6 (3.1)	50.9 (4.5)
11–20 cigarettes day	36.6 (3.0)	30.2 (4.0)
21–30 cigarettes day	6.9 (1.8)	10.7 (1.5)
31+ cigarettes day	4.9 (1.5)	8.2 (2.2)
% Smoke <30 minutes after waking	63.8 (2.9)	39.4 (4.2)
Mean mgs nicotine per cigarette	0.98 (.02)	
% High nicotine brand (≥1.0 mg)	63.1 (3.1)	
% Medium nicotine brand (.7–1.0 mg)	28.3 (2.5)	
% Low nicotine brand (<.7 mg)	8.6 (1.8)	
% Smoking menthol brands (smokers only)	73.3 (2.6)	
% Other tobacco past month:		
Daily	1.2 (0.5)	3.6 (1.8)
Sometimes	9.8 (1.7)	5.3 (0.6)
Never	89.0 (1.8)	91.1 (2.4)
Mean lifetime quit attempts (smokers only)	3.8 (0.2)	
% ≥1 lifetime quit attempt (smokers only)	79.3 (2.5)	
Mean ways cut down (past year or prequit)	2.0 (0.1)	1.4 (0.1)
% cut number of cigarettes	60.8 (2.9)	50.4 (4.4)
% switched to lower nicotine	26.7 (2.6)	16.2 (3.3)
% cut down around others	62.1 (2.9)	39.6 (4.3)
% inhaled less/less of each cig	52.6 (3.0)	37.7 (4.2)
Mean quitting methods tried (past year or prequit)	1.3 (0.1)	1.5 (0.1)
% Any formal treatment	4.1 (1.3)	2.7 (1.3)
group	1.1 (0.6)	0.4 (0.4)
one-to-one	3.3 (1.2)	2.8 (1.3)
% Books/guides	9.2 (1.8)	3.2 (1.4)
% Nicorette	7.3 (1.5)	1.2 (0.9)
% Any drugstore aid	14.2 (2.1)	3.3 (1.3)
filters	12.3 (2.1)	2.4 (1.1)
lozenges	5.9 (1.5)	1.5 (0.7)
% Prayer or meditation	19.0 (2.4)	21.7 (3.4)
% Will power	71.5 (2.8)	89.3 (3.4)
% With smoking-related illness past year	25.4 (2.4)	
% With medical advice to quit past year	35.0 (2.9)	
Mean belief smoking harms health (Scale 0–10)	8.5 (0.2)	
Mean belief quitting improves health (Scale 0–10)	8.5 (0.2)	
Mean desire to quit (Scale 0–10)	7.2 (0.2)	
Mean expected social support for quitting (Scale 0–10)	6.0 (0.3)	
% Seriously thinking of quitting in next year	67.6 (2.9)	
% Interested in free guide from NCM:		
Very interested	64.1 (3.0)	
Somewhat interested	26.4 (2.7)	
Not interested	9.6 (1.8)	

Estimates are weighted to compensate for stratification and nonresponse. No variable missing in ≥10 per cent of cases, except cigarette brand information, missing in 30 per cent of cases. Standard errors are given in parentheses.

Fewer ex-smokers than current smokers reported trying quit smoking books or guides, drugstore aids, or nicotine gum (not available in the US until 1984). More ex-smokers than current smokers reported relying on will power to succeed.

Discussion

The low response rate is obviously troublesome, but the final respondent sample appears reasonably representative of the eligible sample, and survey data were weighted to help compensate for the slight underrepresentation of industrial policyholders, males, and younger male industrial policyholders. Such weighting would not correct for the possibility that policyholders with a greater interest in smoking as a health issue (and/or whose agents were more vigorous in obtaining addresses and encouraging participation) are overrepresented in our respondent sample. Likewise, despite the strong emphasis on confidentiality of results, respondents may have attempted to present their behavior and intentions in a favorable light, particularly given the survey's identification with their insurance company. These factors would serve to create a "best case" bias, limiting generalizability, although probably not greatly limiting the usefulness of the survey to inform the design of quit smoking materials and programs for smokers interested in quitting.

Findings from this study are not directly generalizable to

TABLE 3—Sociodemographic and Smoking History Correlates of Strong Desire to Quit Smoking among Current Smokers (N = 399)

Correlates	Want to Quit = 10 (Scale 0–10) N = 185	Want to Quit = 0–9 (Scale 0–10) N = 214
Sex (% female)	57.8 (3.7)	42.1 (3.6)

Mean expected support for quitting (Scale 0–10)	7.1 (0.3)	5.0 (0.4)
% Very interested in free guide from NCM	87.9 (3.1)	42.1 (4.2)

Estimates are weighted to compensate for stratification and nonresponse. Standard errors are given in parentheses. No variable missing in ≥10 per cent of cases, except mean mgs. nicotine per cigarette, missing in 30 per cent of cases.

TABLE 4—Reasons for Quitting Endorsed by Ex-Smokers (N = 175)

Reason for Quitting	% Endorsing
To feel better physically	77.3 (3.7)
To prevent future illness	63.4 (4.2)
To take more control over my life	53.5 (4.3)
To set example for children/others	42.7 (4.2)
Don't like smell/stains teeth	33.2 (4.2)
To please or help a loved one	29.7 (3.9)
To save money	28.2 (3.9)
So my children wouldn't breathe cigarette smoke	23.0 (3.6)
Because my religion is against it	19.3 (3.3)
Because my doctor told me to	17.3 (3.6)
Because of immediate health problems	17.1 (3.5)
Because my friends don't smoke	8.5 (2.9)
Because of pregnancy (women only)	7.7 (3.1)

Estimates are weighted to compensate for stratification and nonresponse. Standard errors are given in parentheses. No variable missing data for ≥10 per cent of cases.

the general population of Black Americans. Compared to US Black adults 21–60 years, the weighted NCM respondent sample had a slightly higher percentage of females (59 vs 55 per cent); was somewhat older (38 vs 34 per cent of males were older than 40 years, as were 48 vs 36 per cent of females); and had somewhat greater formal education (26.5 vs 29.5 per cent had not completed high school and 36 vs 30 per cent had post-secondary education). It is reassuring that despite the high nonresponse rate the smoking prevalence (36 per cent) and ex-smoking prevalence (14 per cent) estimated for the policyholder population agree fairly closely with the national data (40 per cent and 15 per cent, respectively), suggesting only a small nonresponse tendency among current and former smokers.

Since this paper focuses on smokers and ex-smokers, the comparison of our sample of policyholders to the US by smoking status is relevant. Among current smokers, policyholders had the same sex and age distributions and slightly higher educational levels as for US Blacks (33 vs 37 per cent had not completed high school; 26.5 vs 23.3 per cent had post-secondary education). Among ex-smokers, the proportion of females in NCM was three percentage points higher than for US Blacks, the proportion older than 40 years was substantially greater (67 vs 48 per cent) and the distribution of educational attainment more extreme (31 per cent of policyholders versus 41 per cent of US Blacks had completed high school but not post-secondary education).*** However, the sociodemographic correlates of smoking in this survey (i.e., lower educational level, unemployment, being male, and being unmarried, poorer health status) are similar to those previously identified both for Black Americans[2,3,8] and for the US population as a whole.[2–4] It appears that the higher smoking prevalence among Blacks can be partially accounted for by Black/ White differences in these and other smoking-related sociodemographic factors.[3]

Present findings of a modal low-rate/high nicotine menthol smoking pattern also agree closely with existing data for US Black smokers. Black smokers, both men and women, smoke fewer cigarettes per day than White smokers;[2,4,5,17] in the present study, an estimated 52 per cent of smokers smoked 10 or fewer cigarettes per day. Comparable 1985 HIS figures were approximately 50 per cent for Black men and women smokers, a figure about twice as high as for non-Hispanic White smokers.[2] The 1981 Health Interview Survey found that 65 per cent of Black smokers smoked brands with 1.1 mg or more nicotine (in contrast to only 35 per cent of White smokers), and that 67 per cent of Black smokers smoked menthol cigarettes (in contrast to only 26 per cent of White smokers).[7] The present survey indicated very similar patterns: 63 per cent of smokers smoked brands with 1.0 mg or more nicotine; 73 per cent smoked menthol brands. Likewise, a recent regional study of 457 Black smokers found that three menthol brands (Kool, Newport, and Salem) accounted for nearly 60 per cent of all brands reported.[15] In the present survey, these same three brands accounted for 55 per cent of the brands reported.

Present evidence for relatively high nicotine dependency among Black smokers suggests that low-rate smokers of high nicotine menthol cigarettes may achieve higher than assumed levels of nicotine intake. Menthol cigarettes tend to be higher than non-menthol in tar and nicotine content.[15]

Sociodemographic correlates of quitting motivation in this Black survey population proved similar to those among US smokers in general, including: beliefs in smoking health harms and quitting benefits; recent smoking-related illness; personal medical advice to quit smoking; past efforts to quit or cut down; and expected social support for quitting.[18–20] Likewise, the quitting motives reported by ex-smokers are similar to those for national samples, with health concerns and self-mastery motivation foremost.[18–20] Hence, we would expect Black smokers to benefit from health education messages which emphasize the health harms/benefits of smoking/quitting, note that Blacks are not immune to these effects,[8] and are conveyed using sources, channels and media demonstrated to reach Black audiences.[7]

Past survey data suggest that Black smokers may try to quit as often as White smokers, but may succeed less often.[4,21] Present findings show relatively high quitting motivation and awareness of smoking health harms, and fairly active use of cut-down and self-quitting strategies among the current smokers surveyed.

On the other hand, present results show relatively limited use of beneficial quitting programs and resources by current or ex-smokers. There are, to date, no published data on the extent to which Black and White US smokers may differ in utilization of quit smoking services and resources. However, since Black Americans have more limited access to health care, particularly preventive care,[6] their access to quitting services and resources may also be more limited. Smoking cessation treatment outcomes for Black and White smokers of the same general socioeconomic levels are similar.[22,23] Therefore, improving access to existing treatments through established organizations within the Black community (e.g., churches, fraternal organizations, employers) should prove helpful. However, at the same time, it may be helpful in some circumstances to tailor the content and format of Black-focused treatments for maximum appeal and efficacy. Present findings suggest that such tailoring might:

- challenge possible misconceptions about the safety of low-rate smoking[24];
- introduce nicotine fading strategies designed to help smokers of high nicotine brands prepare for quitting[25];
- include Black ex-smokers as "peer coping models" to help enhance quitting motivation and efficacy[26];
- emphasize practical suggestions for avoiding excessive weight gain after quitting; and
- incorporate only print materials which have been pretested for comprehension and readability if the target audience includes a high proportion of smokers with limited formal education.[27]

American Lung Association Report Says EPA and the States Fail Clean Air Test

A new report from the American Lung Association (ALA) says the US Environmental Protection Agency (EPA) has failed to fulfill its mandate to protect the air Americans breathe. According to the report, EPA's "inadequate enforcement of the Clean Air Act" has allowed many states to weaken, delay, or fail to implement important air pollution control measures. Data were analyzed from nine metropolitan areas considered representative of major urban areas with a variety of air pollution problems from an array of sources.

The ALA report found "significant discrepancies" between many states' projections and actual achievements for air pollution reductions, citing as possible reasons: inaccurate computer models; overly optimistic projections of pollution reductions that would result from specific strategies; and deliberate noncompliance with clean air plans. ALA says that EPA has been lax in enforcing state air pollution control commitments, and states took advantage of it. In general, the states complied with the easier, less expensive controls, ALA pointed out, but not the tough measures Congress mandated.

The ALA report recommends that the next Congress authorize a new, stronger version of the Clean Air Act, giving both EPA and the states stricter guidelines and more resources. The report, *Compliance of Selected Areas with Clean Air Act Requirements*, also recommended that new or improved control measures be added to the Clean Air Act, i.e., stronger tailpipe emission standards; tighter national requirements for vehicle inspection and maintenance; and national regulations for area-wide sources such as dry cleaners, gas stations, architectural coatings, and aerosol sprays. For a full copy or executive summary of the report and a chart of the nine cities, contact American Lung Association, 1740 Broadway, New York, NY 10019–4374. Tel: (212) 315–8700.

A Randomized Trial of a Serialized Self-Help Smoking Cessation Program for Pregnant Women in an HMO

DANIEL H. ERSHOFF, DRPH, PATRICIA DOLAN MULLEN, DRPH, AND VIRGINIA P. QUINN, MPH

Abstract: We report the results of a population-based randomized clinical trial that tested the effectiveness of a prenatal self-help smoking cessation program. The intervention consisted predominately of printed materials received through the mail. The population (n=242) consisted of a socioeconomically and ethnically diverse group of pregnant women enrolled in a large health maintenance organization (HMO) who reported they were smoking at the time of their first prenatal visit. Biochemical confirmation of continuous abstinence achieved prior to the 20th completed week of pregnancy and lasting through delivery revealed 22.2 per cent of the women in the eight-week serialized program quit versus 8.6 per cent of controls with usual care. The adjusted odds ratio was 2.80 (95 per cent CI=1.17, 6.69). We conclude that a low-cost prenatal self-help intervention can significantly affect the public health problem of smoking during pregnancy and its associated risks for maternal and child health. (*Am J Public Health* 1989; 79:182–187.)

Introduction

Smoking during pregnancy is an important modifiable risk factor for low birthweight,[1,2] and is also correlated with increased risk of early fetal loss.[3,4] It is projected that if all pregnant women stopped smoking, the number of fetal and infant deaths would be reduced by 10 per cent.[5] An estimate of the average cost of neonatal care is $189 higher (1983 dollars) for infants born to smokers.[6] Smoking in pregnancy has also been linked to postnatal complications.[7,8,9]

Some 25–30 per cent of US women smoke throughout their pregnancies.[10,11] The earlier a pregnant woman gives up smoking, the lower her excess risk of having a low birthweight infant; smoking cessation early in pregnancy reduces this risk to the same level as that of a non-smoker.[12] Studies conducted to date support the conclusion that higher prenatal quit rates can be achieved through intervention, although the majority of these findings have been limited by either weak methodology, small sample size, or reliance on self-reported outcomes.[13] Furthermore, most of these studies, including the two strongest,[14,15] have used an eighth month point-prevalence measure and therefore they have included some women who may have quit smoking too late in the pregnancy to achieve full benefit from cessation.[16]

This report presents the outcomes of a self-help smoking cessation program in a population receiving prenatal care through a health maintenance organization (HMO). The outcome measure is biochemically confirmed continuous abstinence beginning prior to the 20th week of pregnancy and lasting through delivery.

Methods

Sample and Design

The study design was a prospective randomized control group trial. Intake was conducted from July 1985 through June 1987 among English-speaking pregnant women who obtained prenatal care in one of five health centers of a large multispecialty group affiliated with Maxicare Health Plans, Inc., of Los Angeles, California.

All patients of the medical group began their prenatal care with an individual 45-minute conference conducted by a health educator. Of the total population of pregnant women seeking care, 95 per cent (n=2,382) met the study criterion of being less than 18 weeks pregnant at intake.

Smoking status was obtained at the start of the conference via an item on a self-administered screening questionnaire: "Which of the following statements best describes your smoking habits?" Response categories included: "I smoke now," "I smoke now, but I have cut down since I became pregnant," "I smoke from time to time," "I quit smoking since I became pregnant," and "I don't smoke." Of the 541 prepregnancy smokers (categories 1–4), the study was restricted to the 323 women still smoking ≥7 cigarettes/week. In a random sample of 132 reported non-smokers (category 5), only 4 per cent had biochemical values inconsistent with a non-smoking status.

At the conclusion of the conference, the health educator conducted a two-minute smoking-related interview with the smokers. All patients had been randomized in advance of their visit. Of the smokers, 165 were experimental (E) and 158 were control (C); the health educator was blind to group assignment until the end of data collection. Analyses for this paper are based on the 126 experimental and 116 control women who remained eligible for the study. Attrition resulted from abortion (E=7,C=11), miscarriage (E=12,C=13), disenrollment from the HMO or transfer to another medical group (E=20,C=18).

Intervention

After the smoking-related interview, in keeping with the standard practice of the medical group, all subjects were given a two-page pamphlet on the hazards of smoking during pregnancy and the importance of quitting. The health educator reinforced the written information in a two-minute discussion and answered any questions; she also advised patients of a five-session smoking cessation class available free through the HMO.

Experimental subjects were then given the first of eight self-help booklets, together with a three-minute overview of the program. Women were asked to make a commitment to read Booklet 1 within the ensuing week and to list their reasons for and against smoking. Each of the booklets had such activity assignments designed to personalize the program. The remaining seven booklets were mailed thereafter at weekly intervals and comprised a step-by-step program to

increase motivation for quitting and to teach behavioral strategies for cessation and for relapse prevention. These four- to eight-page booklets, tailored to pregnancy, were printed in black ink on colored paper, had covers illustrated with cartoons depicting multi-ethnic figures, and were written at a ninth grade reading level.[17] They carried the logos of the HMO and medical group. All experimental group women received the program regardless of their motivation to quit smoking or desire to receive the program materials.

Patients had no further contact with the intake health educator. Prenatal care providers were blind to group assignment, and no effort was made to modify their usual counseling practices. Other sources of information on smoking—available through the HMO (e.g., childbirth classes)—were also left unchanged.

Measures

Data were from three sources: the intake conference, a telephone interview conducted at the 26th week of pregnancy, and urine samples routinely collected at each prenatal medical care visit.

The intake conference elicited a medical history, frequency of nausea, information about exposure to passive smoke, and beliefs about the effect of smoking on fetal and maternal health. Additional questions asked of smokers included a brief smoking history, smoking in the current pregnancy, smoking social networks and support, seriousness about quitting, likelihood of quitting, and degree of confidence in ability to quit (Table 1).

The 26th week telephone interview was completed with 94 per cent of the experimental group and 92 per cent of the controls. A standard interview schedule was used to collect data on health-related behavior during the pregnancy. The smoking section, embedded in questions about these other behaviors, included smoking in the past seven days, quit attempts, length of time off cigarettes, and number of slips for those not currently smoking. The interview also assessed the degree to which the experimental group read and used the booklets, satisfaction with content and appearance, and perceived usefulness of the self-help program.

Medical charts were flagged to prompt nurses to retain the urine samples of the study subjects. Patients were usually seen monthly until their ninth month when visits were scheduled each week. On average, seven urine samples were obtained for each subject. After delivery, selected samples were biochemically analyzed for the presence of cotinine, a derivative of nicotine.[18]

Quits reported in the telephone interview were confirmed with all relevant urine samples. A quit was defined as a minimum of seven consecutive days without smoking "even a puff." Additionally, all subjects had a sample from the 34th week of pregnancy analyzed to verify maintenance of a quit or to detect a quit which occurred after the telephone interview. Subjects were classified into the categories of Early Quitter, Middle Quitter, Late Quitter, Early Relapser, Late Relapser, and Non-Quitter. Of primary interest in the current analysis is the group of Early Quitters. These were women who sustained a quit which occurred prior to the 20th week of pregnancy and therefore could derive the greatest benefit from quitting smoking. On average, an Early Quit was based on three urine samples verifying a non-smoking status.

TABLE 2—Smoking Cessation Outcome Classifications

Quit Category	Self-reported Smoking Status at Interview[a]	Selection of Urine Samples Analyzed	Cotinine Cutoffs[b]
Early Quitter	Not currently smoking and the quit began when ≤20 weeks pregnant[c]	All available samples from start of quit through interview + 34th week of pregnancy	At least one value ≤10 ng/ml and no value ≥30 ng/ml[d] + ≤30 ng/ml
Middle Quitter	Not currently smoking and the quit began when >20 and ≤26 weeks pregnant	All available samples from start of quit through interview + 34th week of pregnancy	At least one value ≤10 ng/ml and no value ≥30 ng/ml[d] + ≤30 ng/ml
Late Quitter	Currently smoking and no quit prior to interview	No sample prior to interview 34th week of pregnancy + 35th week of pregnancy[e]	≤10 ng/ml + ≤10 ng/ml
Early Relapser	Currently smoking and a quit prior to interview	All available urines during quit + 34th week of pregnancy	At least one value ≤10 ng/ml and no value ≥30 ng/ml[d] + ≥30 ng/ml
Late Relapser	Currently not smoking and a quit prior to the interview	All available samples from quit through interview + 34th week of pregnancy	At least one value ≤10 ng/ml and no value ≥30 ng/ml[d] + ≥30 ng/ml
Non-Quitter[f]	Currently smoking and no quit prior to interview	No sample prior to interview 34th week of pregnancy	>10 ng/ml

[a]Subjects were asked about their smoking status in a telephone interview conducted in the 26th week of their pregnancy. For the 7% of cases without an interview, classification was based on cotinine values from all available urine samples prior to the 26th week of pregnancy, as well as the 34th week.

[b]Smoking status was determined by assay of urine samples using a version of the gas-liquid chromatography method with nitrogen-phosphorous detection for cotinine.

[c]On average, Early Quitters began their sustained quits in the 11.9th week of pregnancy (S.D. 3.3).

[d]For subjects reporting no puffs during a quit and low exposure to passive smoke, all values prior to the interview had to be ≤10 ng/ml. For subjects reporting at least one slip during the quit or high exposure to passive smoke, some values could be as high as 29 ng/ml although at least one had to be ≤10 ng/ml. (Exposure to passive smoke was assessed by an item from the screening questionnaire: "How much are you exposed to the cigarette smoking of others?" Response categories ranged from 0 "No one smokes around me" to 100 "Others smoke around me all the time." High = 100 for combined responses for home and work.

[e]Due to the self-reported smoking status at interview, a subject was classified as a Late Quitter only if two consecutive urine samples had cotinine values ≤10 ng/ml.

[f]Self-reported quitters with cotinine values which exceeded cutoffs were included in this category (approximately 10% of self-reported quits).

(See Table 2 for a detailed description of the classification methodology.)

Results

Table 1 shows that with the exception of partner's smoking status, the experimental and control groups were similar in background characteristics and in variables with a hypothesized relationship to cessation. The subjects were predominately White, married, in their twenties, and had at least a high school education (mean 12.5 years). The majority had two or more previous pregnancies and entered care for the current pregnancy in the first trimester. At the time of the intake conference, about three-fourths of the sample were smoking ≤10 cigarettes/day with the mean daily consumption half the prepregnancy rate (18.7 versus 9.1). The majority, however, had not quit smoking for as long as 24 hours since becoming pregnant.

Most women were serious about wanting to quit during their current pregnancy but somewhat less confident in their ability to do so. Most women believed that smoking during pregnancy could harm either their own or their baby's health. The majority reported that their partner smoked and about half expected to receive "a great deal" of help if they decided to quit smoking.

Smoking Cessation Outcomes

Table 3 contrasts the study groups by biochemically confirmed category of quitting. The self-help program yielded more than two times the proportion of Early Quitters than

TABLE 3—Smoking Cessation Outcomes by Experimental Status

	% Experimental (N=126)	% Control (N=116)	Difference	95% CI
Early Quitter	22.2	8.6	11.5*	03.0,20.0

0	25.5	13.9	20.7
1+	20.0	6.3	12.9

was observed among controls. Adjusting for the covariates specified in Table 3, the odds ratio was 2.80 (95 per cent CI = 1.17, 6.69).

Late Quitters (subjects who quit in the third trimester) comprised the majority of the other biochemically confirmed quits, providing evidence that some sustained quits do begin close to the end of pregnancy. Only 1 per cent of the total sample was classified as relapsers.

We next examined group proportions of Early Quitters within the context of selected covariates to determine whether the intervention had differential impact for particular subgroups of pregnant women (Table 4). The percentage difference between experimental conditions was about five times as great among light smokers (subjects with a prepregnancy smoking rate <20 cigarettes/day) compared to the heavier smokers. A similar five-fold difference was observed within strata of confidence in ability to quit. In a log-linear model,[19] none of the five interactions was statistically significant at the $p = .05$ level. The failure to detect subgroup differences, however, must be viewed within the context of the very limited power to detect even moderately large interactions.

Process Evaluation

Table 5 provides data on the experimental group's use and evaluation of the program. The vast majority reported reading at least one of the eight booklets, with a mean of 5.8 booklets read, and nearly half (47.7 per cent) reported reading the entire series. The booklets were judged to be interesting, attractive, helpful, and easy to understand. Half of the Early Quitters indicated that the booklets influenced their decision to quit, although a third rated the booklets of "no help at all."

Discussion

Findings from this study indicate that an eight-part series of smoking cessation booklets addressed to the issues of pregnancy were effective in assisting an ethnically and socioeconomically diverse group of pregnant women to quit smoking.

The program raised Early Quit rates in all of the subgroups examined, including those in which women were not likely to quit smoking on their own (those entering care in the second trimester, multiparous women, and those with adverse smoking social networks). While the sample size precluded precise estimation of study effects within subgroups, the observation that the intervention was most effective among women with light prepregnancy smoking rates or with initial high levels of self-efficacy is plausible.

Although our primary interest was in continuous abstinence, other relevant studies to date have measured outcomes with an eighth-month point prevalence. Our study design precluded duplication of this measure; however, combining the Early, Middle and Late Quitter categories provides a close approximation. Using these criteria we found a quit rate of 26.2 per cent in the experimental group, similar to the results achieved in two other trials using rigorous study designs among similar populations. Sexton achieved a quit rate of 32 per cent with an intervention that included one personal visit with a health educator at the time of enrollment, a monthly phone call, and biweekly contact by mail usually in the form of a newsletter.[20] Secker-Walker, *et al*, achieved a cessation rate of 24 per cent among subjects exposed to three individual, 10-to-15-minute counseling sessions with a nurse or health educator; subjects were also given informational materials.*

While it is difficult to draw exact comparisons between studies due to differing patient characteristics, recruitment

*Flynn B: Personal communication, May 1988.

strategies, and practice settings, it appears that this program which used self-help achieved results comparable to those which relied more heavily on personal contact. In contrast to counseling-based programs, self-help interventions in general are easier to implement, can reach a larger target population, and are less costly.

The content of our booklets was similar to other self-help programs; however, the nature of its delivery was unique. Our clinical impression is that the weekly mailings helped keep the women actively involved in their attempts to quit smoking through regular cues to action. Furthermore, women who initially may have been unreceptive to an intervention were afforded an opportunity to benefit from the booklets if their motivation to quit changed during the two-month period.

Another issue not empirically examined but which we believe was helpful was the personalized introduction of the program as a routine part of prenatal care. Women were prescribed the smoking cessation program just as they were their prenatal vitamins, thereby heightening the credibility and impact of the materials.

We have estimated the total costs of the intervention to be approximately $11/patient as implemented in this study (i.e., development and printing costs for 2500 booklets, personnel time and mailing). Had the entire program been provided at one time without a personal introduction, the cost would have been $4/patient.

To date, prenatal smoking cessation interventions in non-welfare populations have yielded quit rates in the range of 25 per cent. Of note, approximately half of the Non-Quitters reported at the 26th week interview that they had quit for at least a day. Therefore, a promising avenue for future research is the development of interventions to convert these unsuccessful attempts into sustained quits.

The model of group-based smoking cessation classes has not proved successful in reaching a wide target population of pregnant smokers. Hughes, *et al*,[21] working with patients receiving care in a hospital outpatient clinic, and Windsor[15] with patients in a public maternity clinic, were unable to induce women to attend such classes. Similarly, in our HMO population we found only 2.4 per cent of patients attended the free classes. In contrast, a self-help program can reach all pregnant smokers.

The simplicity of our program permits its implementation in a variety of health care settings such as medical groups, individual practices, and maternity clinics. The self-help design allows its introduction by a range of medical staff personnel from paraprofessionals to obstetricians. This program offers another effective method of addressing the major public health problem of smoking during pregnancy. The challenge remains for the widespread incorporation of smoking cessation interventions into standard prenatal care.

ACKNOWLEDGMENTS

This research was supported by the National Center for Health Services Research and Health Care Technology Assessment (HS-05128) and Maxicare Health Plans, Inc. The authors wish to thank our project officer, Jean Carmody, for her help throughout the study. We are grateful for the generous support of Dr. Fred Wasserman which was essential to the completion of the project. We gratefully acknowledge the assistance of the medical and administrative staff of Hawthorne Community Medical Group. We are grateful to Dr. Brian Danaher for the original development of the self-help intervention and to Dr. Ellen Gritz and Dr. Barbara Berman for updating and adapting the program for this study. Our thanks to Dr. Jeffery Wilkins and his staff for the biochemical assays of urine samples. Special thanks to the prenatal counselors, Tracy Tobias and Pamela Smith, and Wendy Kalisher, research assistant.

Compensation as a Risk Factor for Lung Cancer in Smokers Who Switch from Nonfilter to Filter Cigarettes

ANSAMMA AUGUSTINE, MD, MPH, RANDALL E. HARRIS, MD, PHD, AND ERNST L. WYNDER, MD

Abstract: The likelihood of increasing the number of cigarettes per day (cpd), a common method of compensation, in smokers switching from nonfilter to filter cigarettes, was examined in newly diagnosed and histologically confirmed lung cancer cases including all cell types: 1,242 lung cancer cases and 2,300 sex and age matched hospital controls were interviewed in 20 hospitals from nine United States cities between 1969 and 1984.

The mean increase in cpd for lung cancer cases was about twice that of controls. Using switchers who did not increase cpd as the referent group, there was a linear dose-response relationship between the odds of lung cancer and increasing level of compensation. The odds ratio increased from 1.19 to 2.37 in males and from 1.66 to 3.83 in females corresponding to increases of 1–10 to 21+ cpd after switching.

Findings from this study suggest that increasing cpd after switching to filter cigarettes is an important risk factor for lung cancer that needs to be emphasized in epidemiologic studies. Proponents of the idea that switching cigarettes is of some benefit, should also advocate that individuals who continue smoking should avoid compensation after switching. (*Am J Public Health* 1989; 79:188–191.)

Introduction

Epidemiologic studies have shown a reduced risk for lung cancer among smokers who switch from nonfilter to filter cigarettes relative to those who continue smoking nonfilter cigarettes.[1] On the basis of this finding it has often been recommended that people who are unwilling or unable to give up smoking should switch to filter cigarettes. The tar intake per day after switching to filter cigarettes will be reduced if smokers continue to smoke the same or fewer numbers of cigarettes per day (cpd). In this paper the term "switchers" stands explicitly for smokers who switched from nonfilter to filter cigarettes. The ways by which switchers attempt to compensate for the reduction in nicotine are by increasing cpd or altering their puff frequency, puff duration, puff rate, and interpuff interval[2] exposing themselves to higher quantities of gas and particulate cigarette smoke constituents.[3] This study focuses on compensation in switchers who increase cpd among lung cancer cases and controls. The main questions of interest were: Is there a differential pattern of increase in cpd between cases and controls? Is there an increase in risk for lung cancer in switchers who increase cpd compared to those who do not?

Methods

The cases and controls in this study were interviewed between 1969 and 1984, in 20 hospitals in nine US cities, as part of a hospital-based ongoing study of smoking-related cancers.[4] In the original study, cases were patients with newly diagnosed and histologically confirmed tobacco-related cancers and controls were hospitalized patients with an admitting diagnosis consisting of conditions not thought to be related to smoking. The exclusion of smoking-related conditions from control diagnoses was intended to reduce potential bias in the assessment of risks due to cigarette smoking. For the purpose of this study, we took lung cancer cases of all cell types and controls from this data pool. Controls had cancers of other organs and non-neoplastic diseases. The smoking-related cancers excluded from control diagnoses were cancers of the oral cavity, larynx, nasopharynx, kidney, bladder, oesophagus, salivary gland, pancreas and liver; patients with heart disease, stroke, peripheral vascular disease, chronic bronchitis, emphysema, gastrointestinal ulcer, and cirrhosis were also excluded.

All study subjects were interviewed in the hospital by trained interviewers using a structured questionnaire that included sociodemographic variables, lifetime smoking history, cpd, brands of filter and nonfilter cigarettes smoked. For each individual, the average cpd of filter cigarettes was calculated by summing up the cpd for all filter brands and then dividing by the number of filter brands. The average cpd of nonfilter cigarettes was calculated similarly.

As a partial validation procedure, we checked the reliability of the initial smoking data by recontacting 100 cases and 100 controls, selected at random following their discharge from hospital.

In this investigation, only those who were current cigarette smokers and who had switched from nonfilter to filter cigarettes were considered. A current smoker was defined as someone who had smoked at least one cpd for a continuous period of one year or more and was also smoking within the year preceding diagnosis. Those cigarette smokers who smoked cigars or pipes concurrently were excluded. Cases were frequency matched at approximately a 1:2 ratio on sex and age at diagnosis (± 5 years) to controls.[5]

Statistical Techniques

All statistical analyses were performed separately by sex. Paired cpd data before and after switching were used to assess the change in cpd. Mean changes in cpd after switching for cases and controls were adjusted by linear regression for age at switching and duration of nonfilter cigarette smoking utilizing analysis of covariance.[6] Adjusted means for cases and controls were compared by t-tests using the error mean square from the analysis of covariance with the appropriate degrees of freedom.[6,7]

Logistic regression analysis[8] was used to estimate the odds ratio for lung cancer in those who compensated (increased cpd) relative to those who did not compensate. An unmatched analysis was performed with adjustments for nonfilter cpd, duration of nonfilter and filter cigarette smoking, and age at diagnosis or age at switching. Since our study was limited to switchers, all subjects had corresponding sets of time points in their smoking histories (age at start, age at

© 1989 American Journal of Public Health 0090-0036/89$1.50

switch, and age at diagnosis), thereby facilitating simultaneous adjustment for the same potential confounders in multiple logistic models. In this paper, we restrict the term "compensation" to mean an increase in cpd after switching to filter cigarettes.

Multiple linear regression analysis[6] was performed among controls to determine if cpd after switching could be predicted by variables such as age at switching, nonfilter cpd, nonfilter duration, and tar yield per day before switching.

Results

A total of 781 male and 461 female lung cancer cases of all cell types and 1,432 male and 868 female controls were studied; all subjects were smokers who had switched to filter cigarettes. Among male switchers, 45 per cent (n = 351) of cases and 41 per cent (n = 580) of controls increased cpd; 42 per cent (n = 327) of cases and 44 per cent (n = 634) of controls smoked the same number of cpd; and 13 per cent (n = 103) of cases and 15 per cent (n = 218) of controls decreased cpd. Among female switchers, 59 per cent of cases (n = 272) and 48 per cent of controls (n = 418) increased cpd; 31 per cent (n = 143) of cases and 41 per cent (n = 356) of controls smoked the same number of cpd; and 10 per cent (n = 46) of cases and 11 per cent (n = 91) of controls decreased cpd.

The maximum reduction after switching among cases and controls was about 50 cpd in males and 60 cpd in females. The maximum increase noted ranged from 50–70 cpd in males and 50–60 cpd in females. In both males and females, the interquartiles (25th to 75th percentiles) ranged from 0–15 cpd in cases and 0–10 in controls.

Distributions of cases and controls by age, education, marital status, religion, and occupation are presented in Table 1. In both males and females, case-control differences were not evident in the sociodemographic variables. Mean ages at diagnoses for males were 57.0 years in cases and 56.1 years in controls. The corresponding ages for females were 56.8 years and 55.8 years.

Mean values of duration of smoking and cpd are shown in Table 2. On the average, both male and female cases had smoked nonfilter cigarettes 1.5–2 years longer than controls. In males, cases and controls smoked approximately the same duration of filter cigarettes while female cases smoked approximately one year longer than the controls. On the average, cases of both sexes smoked about 5 to 6 more cpd than the controls before switching, and about 8 more cpd than the controls after switching. Notably cases showed greater compensation than controls, the mean increase in cpd for cases being about twice that of controls. Adjustments for the differences between cases and controls in duration of nonfilter cigarette smoking, age at switching and age at diagnosis by analysis of covariance did not alter these results.

Mean values of cpd before and after switching by cpd classes before switching (1–10, 11–20, 21–30, 31–40 and 41+) are presented in Table 3. Three points are evident from these data. Most importantly, cases showed greater average compensation than the controls in each cpd class and the differences in compensation between cases and controls within classes were especially great for all the classes in males and for the first four classes in females. Compensation in cpd was evident only when the initial cpd was less than 30. When initial cpd was greater than 30, there was a tendency either not to increase or even to decrease cpd after switching. In both cases and controls, the extent of compensation progressively declined with increasing cpd before switching. The difference in cpd after adjustments using analysis of covariance for age at switching and duration of nonfilter cigarette smoking did not alter these results appreciably.

Table 4 shows a clearcut dose-response relationship for lung cancer with increasing cpd levels (compensation) in both

[a]Difference in cpd = Filter cpd − Nonfilter cpd

sexes. The odds ratios increased from 1.19 to 2.37 in males and 1.66 to 3.83 in females corresponding with increases of 1–10 to 21+ cpd after switching.

The odds ratio associated with increasing cpd versus decreasing cpd after switching, relative to those who did not change cpd, was also examined. Compared to those who did not change their cpd, those who increased cpd had an odds ratio of 1.38 (95 per cent confidence intervals = 1.31, 1.69) in males and 2.19 (95 per cent CI = 1.67, 2.89) in females after adjusting for confounders. In contrast, males who decreased cpd had a reduction in the odds ratio to 0.64 (95 per cent CI = 0.47, 0.86); in females, the number of cases who decreased cpd was small (n = 46) and the corresponding odds ratio was 0.97 (95 per cent CI = 0.62, 1.55).

Since greater compensation occurred among those who initially smoked ≤30 cpd (Table 3), we examined the risks associated with increasing cpd according to those who initially smoked ≤30 cpd and >30 cpd. Among those who initially smoked ≤30 cpd, those who increased cpd had elevated odds ratios of 1.34 (95 per cent CI = 1.08, 1.65) in males, and 1.84 (95 per cent CI = 1.42, 2.38) in females for lung cancer, relative to those who did not increase cpd, after adjustments for age at switch, duration of nonfilter and filter cigarette smoking. Among those who initially smoked >30 cpd, the corresponding odds ratio was also elevated in males: OR = 1.67 (95 per cent CI = 1.08, 2.57); in females, OR = 0.94 (95 per cent CI = 0.37, 2.41); the numbers of cases (n = 59) and controls (n = 48) were relatively small.

[a]Adjusted for nonfilter duration, filter duration, nonfilter cpd, and age at switch.
[b]Test of linear trend significant at $p < 0.05$.
*Referent category.

The regression of compensation (filter cpd − nonfilter cpd) on nonfilter cpd yielded negative slopes, indicating that nonfilter cpd was a negative predictor of compensation, i.e., the lower the initial cpd, the greater the compensation.

Linear regression analysis among controls was performed to examine the effect of selected variables in predicting cpd after switching. Results were similar for males and females. Cigarettes per day before switching ($\beta = 0.7$, S.E. = 0.03) and age at switching ($\beta = 0.2$, S.E. = 0.03) predicted cpd after switching in linear regression models. These variables together accounted for 34 per cent and 39 per cent of the variability among males and females, respectively, while duration of nonfilter cigarette smoking, tar yield per day before switching, and age at start of smoking accounted for little or none of the variability.

Discussion

The results of this study indicate that a sizable portion of smokers tend to compensate (increase cpd) after switching from nonfilter to filter cigarettes and that patients with lung cancer compensate more than controls. A greater proportion of females (50–60 per cent) than males (40–45 per cent) showed compensation in cpd. Among switchers who increased cpd, there was a linear dose-response relation between the odds of lung cancer with increasing level of compensation. The linearity of the dose response pattern in both sexes supports the biological plausibility of compensation as an important risk factor for lung cancer. We emphasize that these results are adjusted for past smoking patterns and duration differences.

In our study, the lower the initial cpd, the greater the tendency to compensate by increasing cpd. In fact, heavy smokers of nonfilter cigarettes (>30 cpd) on the average tended to decrease rather than increase cpd after switching to filter cigarettes. There may be several explanations for this finding. It is possible that heavy smokers may compensate by altering their smoking topography since there may be a time limitation (less leeway) in smoking additional cigarettes and/or encumbent symptoms might compel them to smoke less upon switching. A similar finding was noted in the 13-year follow-up survey by the American Cancer Society.[9] Lighter smokers (not separated by switch status) of less than half a pack a day in 1959 showed an average increase in cpd by 1972 which doubled that observed in heavier smokers. Another plausible explanation relates to an upper threshold phenomenon of nicotine dependency. In the already heavy nonfilter cigarette smokers (>30 cpd), the amount of filter cigarettes smoked (even when it is less than the initial cpd) after switching may be sufficient to maintain their required nicotine level.

One possible source of bias in this study is recall bias. If cases overestimated their exposure, while controls underestimated it, then the risk will appear larger than real. As a partial validation procedure, we reinterviewed 100 cases and 100 controls following their discharge from hospital. The results from the second interview showed good agreement with first reported cpd in both groups (average correlation 0.90) and revealed no differential reporting between cases and controls. The average difference between first and second interviews for both cases and controls was only one cpd.

The major reason for limiting our analysis to switchers only was to facilitate adjustment for the corresponding sets of confounders (duration of nonfilter smoking, age at switch, and duration of filter smoking) within the comparison groups, i.e., switchers who did not compensate, using multiple logistic analysis. Since there is also intense interest in comparing switchers with exclusive nonfilter cigarette smokers, we attempted to assess their patterns of odds ratio. Wynder and Kabat[10], observed minimum odds ratios for lung cancer of 0.66 and 0.74 in males and females, respectively, among switchers who had smoked filter cigarettes for more than 10 years, relative to exclusive nonfilter smokers. Assuming that 0.66 and 0.74 represent the odds ratios among male and female switchers who increased by 1–10 cpd after switching (this was the median class of cpd change in our study), we computed odds ratios due to various levels of compensation relative to nonfilter cigarette smokers (Figure 1). Further reductions in odds ratios are evident with no compensation (0.55 and 0.45 in males and females, respectively), whereas for switchers who compensate, the odds ratios increase in a linear fashion, and even become greater than that of nonfilter only smokers when the compensation level exceeds 20 cpd.

Compensation as a risk factor has not been stressed in epidemiologic studies comparing the health risk of nonfilter to filter cigarette switchers relative to exclusive nonfilter cigarette smokers. Compensation is undoubtedly a complex phenomenon. It includes changes in puff frequency, duration, rate and interval[2]. Nevertheless, the relatively simple measure of compensation used in this study (increase in cpd after switching) has proved to be an important risk factor for lung cancer in itself. Based on our results, the lung cancer risk among smokers who switch to filter cigarettes would be reduced further if they strive not to increase cpd after switching. Proponents of the idea that switching cigarettes is of some benefit should also advocate that individuals who continue smoking should avoid compensating after switching.

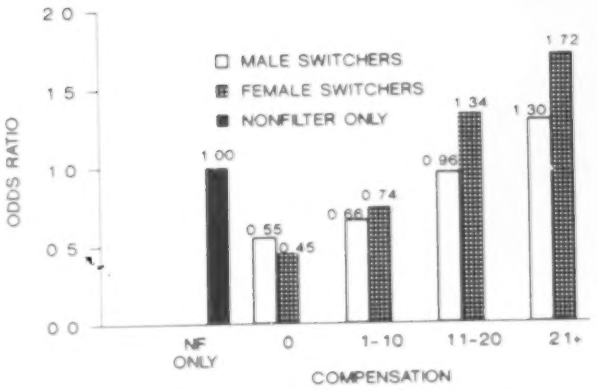

FIGURE 1—Risks among Switchers Relative to Nonfilter Only Smokers According to Different Levels of Compensation.*

*Compensation is the increase in cigarettes per day after switching to filter cigarettes.

A Comparative Evaluation of a Restrictive Smoking Policy in a General Hospital

Lois Biener, PhD, David B. Abrams, PhD, Michael J. Follick, PhD, and Larry Dean, BA

Abstract: The impact of a restrictive smoking policy on the behavior and attitudes of smokers and non-smokers was assessed by surveying random cross-sectional samples of hospital employees before, six months after and 12 months after the policy was implemented, and comparing responses with those of employees of a hospital with no restrictive policy. Effectiveness of policy implementation was also evaluated. Results indicated that the policy was well-publicized and was approved by virtually all the non-smokers and the majority of the smokers. Following implementation, employees in the smoking policy hospital were less likely to report being bothered by smoke at their work stations than were employees of the comparison hospital. Six months and one year after the policy change, smokers reported lower smoking rates while at work, although quit smoking rates and home smoking rates were similar in both hospitals. (*Am J Public Health* 1989; 79:192–195.)

Introduction

The Surgeon General's Report on involuntary smoking concludes that environmental tobacco smoke is hazardous to the health of non-smokers and that employers are obligated to protect workers from risk due to exposure.[1] In spite of the fact that many restrictive smoking policies were adopted by worksites in the 1980s,[2] most evaluations consist of casual samples of the target worksite[3] and/or retrospective reports of pre-policy behavior and attitudes.[4,5] The research reported here examined the impact over 12 months of a restrictive smoking policy adopted at one general hospital relative to a comparison hospital where no restrictive policy was implemented.

Methods

The Settings

Both institutions in this study, the Miriam Hospital (policy hospital) and the Roger Williams General Hospital (comparison hospital), are university-affiliated general medical facilities with approximately 250 beds and 1,400 employees. Before the initiation of the policy change, both hospitals had several designated no-smoking areas, and smoking was permitted in most offices and staff lounges as well as in the smoking section of the cafeteria. Patients and visitors could smoke in designated lounges on each floor and in patient rooms as long as fire safety rules were not violated.

Eight months prior to the implementation of the restrictive policy, the Employee Health Nurse brought the issue to the Safety Committee of the Miriam Hospital. During the following five months a subcommittee solicited feedback from department heads. The subcommittee eventually proposed that smoking by employees and visitors be prohibited throughout the building except for two designated sections of the hospital cafeteria and in the coffee shop. Patients would be permitted to smoke in their rooms if their roommate did not object, but smoking would no longer be permitted in patient lounges. In the interim, a new hospital president was installed who strongly supported the restrictive policy. He mandated that it be announced by July 1 and take effect on August 1, 1985.

In July a notice was included in all employees' paychecks that presented the health rationale for the policy, and stated that it would be enforced by managers and department heads in the same manner as any other issue relating to appropriate employee behavior. It also stated that free quit smoking programs would be offered on-site to employees who would like help in stopping smoking. Self-help smoking cessation programs were offered at both the policy and the comparison hospitals in the fall of 1985 as part of a larger study to be reported elsewhere.

Sampling Design

Lists were obtained of all full-time employees of the two hospitals prior to the implementation of the smoking restrictions at the policy hospital. Random cross-sectional samples were drawn without replacement from each employee list at the three assessment points: one month prior to the policy change, six months after the policy change, and 12 months after the policy change. The intention was to sample 85 employees at each hospital at each time period, under the assumption that this would yield approximately 25 smokers per sample. However, since the six-month assessment yielded only 14 smokers at the policy hospital and 18 at the comparison hospital, the sampling frame was increased to 120 employees for the 12-month assessment. The additional employees were selected from the same list of those employed at the pre-policy period. In addition to the six cross-sectional samples, a cohort of 85 individuals at each hospital was selected to be followed over the three assessment periods. There was substantial attrition from the cohort due to turnover in the labor force, vacations, and refusals. Only 71 per cent of the policy hospital cohort and 63 per cent of the comparison cohort could be re-interviewed at the final assessment period. At the policy hospital, smokers were more likely than non-smokers to refuse to be re-interviewed (seven of the 23 smokers contacted refused, versus one of the 45 non-smokers contacted; 95 per cent confidence interval for the difference between the two proportions: .06, .51). At the comparison hospital, the rate of refusal was unrelated to smoking status. Although trends for the results in the cohort were similar to those reported for the cross-sectional sample, biased attrition of the smokers in the policy hospital render their data uninterpretable. Therefore only data from the cross-sectional sample are presented in this report.

Data Collection and Analysis

Four research assistants, trained and supervised by the first author, conducted telephone interviews with employees during working hours. Questions specific to the policy change were asked only of policy hospital employees (i.e., those measuring awareness and approval of the policy, perceptions of non-compliance and perceived effects of the policy on performance.) All other questions were asked of employees of both hospitals.

Measures taken only in the policy hospital or at both hospitals at only one time period were examined as proportions. Where appropriate, differences between groups were tested by examining differences between proportions and the 95% CI for the difference.[7] Measures taken at both hospitals at the three assessment periods were analyzed with log linear analyses (when the outcome variable was categorical) and with multiple regression analysis when the outcome was continuous (i.e., number of cigarettes smoked.) In either case, the effect of the policy change was assessed by entering the following predictors simultaneously: *Hospital* (policy hospital = 1; comparison hospital = 0); *Pre/Post-Change* (pre = −2, six months = 1, 12 months = 1), *Post/Policy-Change* (pre = 0, six months = −1, 12 months = 1); and the interactions *Hospital by Pre/Post-Change* and *Hospital by Post/Policy-Change*. The main effects estimate pre-existing differences between the hospitals as well as secular changes in the community at large. If the policy change had an impact independent of those effects, it would be detected in the interaction Hospital by Pre/Post-Change. If the effect either diminished or increased with time, it would be detected in the interaction Hospital by Post/Policy-Change.

Results

Table 1 shows the number of respondents interviewed at each hospital by time period. The refusal rates ranged from 2 to 9 per cent. Respondents were virtually identical to the employee populations from which they were drawn in sex (70 per cent female); average age (38 years); and occupational status (45 per cent professional and managerial). Characteristics of the samples from the two hospitals collapsed over the three time periods are presented in Table 2.

Almost all of the respondents at the policy hospital reported awareness of the smoking restrictions and could name the places where smoking was permitted. Over 90 per cent of the smokers and two-thirds of the non-smokers thought that the restrictive policy was "a good idea." Although half the respondents reported being aware of at least one instance of non-compliance with the policy, only 12 per cent and 16 per cent (at six and 12 months, respectively) reported more than "a few" instances. When questioned at 12 months about the effect of the policy on their performance, the majority of both smokers and non-smokers felt that it had had no effect. However, none of the smokers felt that their work had improved as compared to 21 per cent of the non-smokers who stated the improved air quality helped them to concentrate better. On the other hand, none of the non-smokers felt that their performance had deteriorated as compared to 19 per cent of the smokers.

At the 12-month assessment period, non-smokers at both hospitals were asked whether they were bothered by smoke in several areas of their workplace. Five per cent of the non-smokers at the policy hospital reported being bothered by smoke in offices compared to 25 per cent at the comparison hospital (95 per cent CI for the difference: 8,32). Results were comparable for staff lounges but the proportion of non-smokers bothered by smoke in the lavatories was similar for both hospitals (18 per cent and 16 per cent). Non-smokers were also asked to indicate what they would do if they were bothered by a coworker's tobacco smoke. Responses were coded as "assertive" if they involved saying something directly to the smoker—for example, mentioning that the smoke was bothersome. Other responses were coded as "unassertive", for example, doing nothing. Approximately half of the non-smokers at each hospital indicated that they would respond assertively.

Effect of Policy on Smoking

At each assessment period, smokers at both hospitals were asked to indicate the extent to which they agreed with the statements: "My coworkers disapprove of my smoking" and "My smoking affects the health of others." As Table 3 indicates, there was little change in response to these questions as a function of time period and little difference in response patterns in the two hospitals.

Very few smokers in the sample reported having quit during the year following the policy change. Among those individuals who reported having been smokers in August of 1985, 7 per cent at the policy hospital and 11 per cent at the comparison hospital reported quitting by one year later. Table 3 shows reports of having made a serious quit attempt in the prior six months as well as reported intentions of

quitting in the next six months. The striking difference between hospitals in the baseline level of reported quit attempts is difficult to explain. Nevertheless, according to the log linear analyses the restrictive policy had no effect of consequence on reports of quit attempts. The policy change does appear to have increased intentions to quit in the short run. This trend reversed itself by 12 months after implementation. Log linear analysis using the model described above indicates that the interaction Hospital by Post/Policy-Change was significant at the .05 level.

The effect of the policy change on smoking rate was assessed by examining the number of cigarettes smoked per day while at work, before and after work, and on non-work days with the multiple regression model described above. Age, gender, and years of education were controlled. The results of these analyses demonstrated that the number of cigarettes smoked during work decreased at the policy hospital after the restrictive policy was implemented while no such change occurred at the comparison hospital [Hospital by Pre/Post-Change: b = −1.485; standard error (b) = .664; 95 per cent CI = −2.80; −0.17]. There was no apparent effect of the policy on the number of cigarettes smoked outside of work or on non-work days. The passage of time after policy implementation had no additional effect on smoking rates. Table 4 shows the unadjusted means for the three smoking rates (age, gender, and education did not account for substantial portions of variance in smoking rates).

Records of the self-help smoking program offered at both hospitals soon after the baseline assessment indicate that the policy did not lead to an increase in the enrollment of smokers. Thirteen per cent of smokers at the policy and 14 per cent at the comparison hospital enrolled in the program.

Discussion

Other studies have also reported high rates of approval for restrictive policies, even among smokers.[3,6] In only one published report did a majority of the smokers disapprove of smoking restrictions.[5] In that case the policy created a total ban on smoking and the implementation strategy apparently left many of the smokers confused about their role in the

decision-making. Employers' concern about severe dissension between smokers and non-smokers has been identified as a major barrier to the implementation of restrictive smoking policies at the worksite. The results of the present study can be added to the mounting evidence that smoking can be restricted at the workplace without undue conflict or dissatisfaction.

The results suggest that restrictive policies do lead to a reduction in self-reported smoking behavior sustained for up to 12 months after implementation. Furthermore, smokers who reduced their smoking at work did not seem to compensate for their reductions by increasing their smoking outside of work as theories of nicotine dependence might predict.[8,9] The fact that different individuals were surveyed at each assessment requires that some caution be used in interpreting the results. However, analysis of the effects of shifts in the demographic composition of the samples (i.e., shifts in age, job status, and education) indicate that patterns of smoking and quitting cannot be attributed to these shifts. Although the present study, as well as previous work, lacks biochemical validation of reports of smoking behavior, the validity of smokers' reports is bolstered by non-smokers report of less annoyance from second-hand smoke.

The present results do not support the expectation that restrictive policies will increase the rate of smoking cessation either by making non-smokers less tolerant of smokers, or by directly affecting the motivation and/or quitting efforts of smokers. Our ability to detect effects on smoking behavior is limited by the small number of smokers in our sample, so this conclusion must be seen as tentative. However, the fact that enrollment in a free worksite-based self-help program was similar in the two hospitals can be seen as an additional indication that smokers' motivation to quit was not influenced by the policy. Furthermore, only one published study reports high rates of quitting subsequent to a restrictive policy,[3] and that finding is limited by the non-representativeness of the sample and the lack of a control group. The fact that intentions to quit increased shortly after the policy was implemented, and then decreased to below baseline levels may indicate that smokers expect that restrictive policies will require them to quit. When they learn that they can adapt, by going to the remaining smoking areas and by reducing the number of cigarettes smoked at work, the motivation to quit may be undermined. If so, the most opportune time for a quit smoking campaign may be during the early phases of a policy change.

It has been expected that restrictive policies will mobilize non-smoker pressure on smokers, yet 50 per cent of the non-smokers report being reluctant to ask a co-worker to refrain from smoking in their presence. Furthermore, to the extent that a policy is successful in reducing non-smokers' exposure to smoke, they may find even less need to put pressure on smokers and this potential source of motivation to quit may decrease.

Research to date suggests that no single intervention in isolation is sufficiently powerful to treat a severe addiction like smoking. Dramatic reductions in smoking prevalence may require multifaceted interventions including environmental restrictions, incentives to quit and treatment programs targeted to specific subgroups.[10] Nevertheless, reductions in rate of smoking over 12 months is a promising result of restrictive policies, and worksites still have potential for contributing to the goal of a smoke-free society.

ACKNOWLEDGMENTS

This research was funded by NCI Grant #CA 38309. The authors would like to thank the staff of the Miriam Hospital and the Roger Williams General Hospital for their generous support of this research. The research team Catherine Draycott, Lisa John, and Elyse Moore contributed substantially to this work. Special thanks are extended to Robert Stout for his helpful consultation on statistical methods.

Cigarette Smoking among San Francisco Hispanics: The Role of Acculturation and Gender

Gerardo Marin, PhD, Eliseo J. Perez-Stable, MD, and Barbara Vanoss Marin, PhD

Abstract: We conducted a phone survey of 1,669 San Francisco Hispanics ages 15 to 64 years. The age-adjusted overall smoking prevalence was 25.4 per cent (95% CI = 23.3, 27.5) with more men (32.4 per cent) smoking than women (16.8 per cent). Age-adjusted smoking rates were higher among the less acculturated males (37.5 vs 26.7 per cent) and among the more acculturated females (22.6 vs 13.6 per cent). The more acculturated, however, smoked a greater number of cigarettes per day independent of gender. Community-based smoking cessation interventions, adapted to local conditions, may have a greater potential for success among Hispanics. (*Am J Public Health* 1989; 79:196–199.)

Introduction

Most studies on cigarette smoking among Hispanics indicate that although the overall prevalence is lower than the rates for non-Hispanics Whites, Hispanic men smoke more than Hispanic women.[1–7] The level of acculturation to the mainstream US culture may play a significant role in influencing cigarette smoking behavior. However, the relationship between acculturation and smoking prevalence remains unclear, in part due to the fact that instruments used to measure acculturation have usually been plagued by serious psychometric shortcomings.[8] The southwest portion of the Hispanic Health and Nutrition Examination Survey (HHANES)* showed that 28 per cent of women scoring in the upper tertile of an acculturation scale reported current smoking, compared to 19 per cent of those scoring in the lower tertile of acculturation. Among the men sampled in the HHANES, the level of acculturation was not consistently related to cigarette smoking. In contrast, a recent study among a representative sample of older Mexican Americans and of their relatives residing in San Antonio, Texas showed that acculturation was not related to prevalence of smoking.[3]

To evaluate the role of acculturation in cigarette smoking behavior, we conducted a phone survey of a representative sample of Hispanics in San Francisco.

Methods

Respondents were sampled using Waksberg's[9] method for random digit dialing from the 27 census tracts in San Francisco with 10 per cent or more Hispanic residents. These tracts represented 66.6 per cent (N = 55,541) of all Hispanics (N = 83,373) living in the city of San Francisco according to the 1980 census.[10] Participants were given a choice of answering the interview in either English or Spanish; 67 per cent preferred to be interviewed in Spanish. The refusal rate (proportion of eligible respondents contacted who declined to be interviewed) was only 4.7 per cent. Hispanic ethnicity was defined by self-identification.

The interview schedule asked about current and past smoking behavior, awareness of smoking cessation programs, standard sociodemographic items, and a five-item acculturation scale developed by Marin and colleagues which has shown excellent reliability and validity.[8]

Data were analyzed using standard techniques. Age-adjusted rates were calculated by direct standardization method[11] using the 1980 Hispanic population in San Francisco as reference.

Results

A total of 1,669 Hispanics, between 15 and 64 years of age, were interviewed by telephone between October 1986 and March 1987. The respondents' had a mean age of 35.5 years (SD = 12.06), an average of 11.6 years of education and had lived in the United States a mean of 14.2 years; 69.5 per cent were born in Latin America. Interviewed Hispanics were of Mexican (36.4 per cent), Central American (46.9 per cent), South American (6.1 per cent), or Caribbean (10.6 per cent) background.

A total of 735 (44 per cent) respondents (95% confidence intervals = 41.6, 46.4) reported smoking at least 100 cigarettes in their lives. The overall age-adjusted prevalence of current smoking (Table 1) was 25.4 per cent (95% CI = 23.3, 27.5) but only 16.8 per cent (95% CI = 15.6, 18.0) of the women compared to 32.4 per cent (95% CI = 29.4, 35.4) of the men were currently smoking. Less acculturated men had a higher age-adjusted smoking rate than the more acculturated (37.5 vs 26.7 per cent), while the reverse relation held with women (13.6 vs 22.6 per cent).

The more highly acculturated Hispanic smokers reported smoking an average of 13.3 cigarettes per day compared to 8.6 cigarettes per day among the less acculturated and waiting an average of over 90 minutes less than those with

*Rates for current smoking are age-adjusted using the 1980 Hispanic population in San Francisco as reference.

lower levels of acculturation before lighting their first cigarette of the day (Table 2).

The less acculturated respondents tended to report quitting plans to a greater extent than the more acculturated (Table 3). For example, the mean number of quit attempts reported for the 12 months prior to the interview was 2.0 for the less acculturated compared to 1.4 for the more acculturated. Less acculturated male smokers also reported 22 more days without smoking in the previous year, but among women there was virtually no difference. The highly acculturated felt more certain than the less acculturated about how to obtain information dealing with smoking cessation and about where to join a cessation group. However, all Hispanic smokers interviewed reported having heard information on the health dangers of smoking in a similar proportion.

Discussion

The results of this survey of San Francisco Hispanics are consistent with other published reports that have shown marked differences in smoking prevalence due to the gender and acculturation level of the respondents.[1-7] Our data also indicate a lower smoking prevalence than found in regional surveys[3,6,*] completed several years ago. This may actually represent a trend toward decreasing smoking prevalence

among Hispanics since our rates (32.4 per cent for men and 16.8 per cent for women) are similar to those reported for Hispanics in the 1985 National Health Interview Survey[7] (31 per cent and 21 per cent, respectively).

However, several limitations of this study must be considered. First, although the majority of San Francisco Hispanics live in the area included in the survey, the sample may not be representative due to the 66.6 per cent coverage. Second, deception in self-reporting cigarette smoking behavior has been reported among New Mexico Hispanics,[12] and thus the low smoking prevalence found here may be an underestimate. Third, Hispanics in San Francisco live in a strong anti-smoking environment and thus may be influenced to an extent that limits generalizability to Hispanics in other areas. Finally, the acculturation scale applied is a unidimensional measure of a complex phenomenon that is otherwise difficult and tedious to evaluate.

Despite these limitations, the observed differences in prevalence and smoking behavior by the respondents' level of acculturation are consistent with the concept that as individuals adapt to a new culture their attitudes and behaviors also change.[13] These data indicate that the influence of acculturation on smoking prevalence and behaviors varies by gender. Our observation that increased acculturation among men results in decreased smoking, and that the opposite effect is seen among women, may reflect current social norms for smoking in the United States. In addition, the number of cigarettes smoked per day and other smoking behaviors of the more acculturated Hispanics resemble those of non-Hispanic White smokers.

Future prevention and cessation programs directed at Hispanics will need to consider the influence of acculturation on the prevalence and smoking behaviors of prospective clients. In addition, the less acculturated, primarily Spanish-speaking Hispanic seems to be in greater need of information and services. A majority of Hispanics report being light smokers[1,3,*] implying that less intense cessation methods may be expected to have a greater impact among them. Thus large-scale community programs utilizing Spanish-language mass media with information on the dangers of smoking and including simple

cessation techniques that smokers with low levels of addiction can utilize to quit smoking need to be a priority. The need to target the less acculturated Hispanic men, as the subgroup with the highest prevalence, is a challenge to program planners who will need to deal with stereotyped beliefs regarding smoking among the members of this group.[14]

Evidence for Limits on the Acceptability of Lowest-Tar Cigarettes

LYNN T. KOZLOWSKI, PHD

Abstract: The sales of the lowest yield cigarettes (1-3 mg tar) seem to have been particularly resistant to the effects of promotion and advertising, while the sales of other low-yield cigarettes (4-9 mg tar) seem to have been increased by promotional efforts. This finding is consistent with the existence of a boundary of tar and nicotine acceptability below which consumers in general are not prepared to go. Use of lower tar cigarettes may be helpful for those who cannot stop smoking, but, since 1979, the percentage of cigarettes under 16 mg tar has changed little. (*Am J Public Health* 1989; 79:198–199.)

Introduction

There may be limits to consumer acceptability of the lowest-yield cigarettes.[1,2] Although these cigarettes have been promoted (sometimes as less hazardous), they have attracted few customers.[2] From information provided by the cigarette industry, the United States Federal Trade Commission (FTC) has reported the promotional costs and sales of cigarettes as a function of tar yield categories for the years 1979 to 1986[3,4] (see Table 1). The relation between promotional costs and sales is least ambiguous when promotional costs are increasing: Other things being equal, greater promotion should be reflected in greater sales. When promotional costs drop, brand loyalty and other habitual pressures can account for much of the repeat purchasing. I therefore assessed the relation between promotion and sales for the three consecutive years in which promotional costs were increasing (1979 through 1981) for each of the three lowest-yield categories of low-tar cigarettes.

Method

Advertising and promotional expenditures include advertising in newspapers, magazines, paperback books, outdoor billboards, transit posters, and at point of sale, as well as promotional allowances, sampling and other distribution, sponsorship of special events, and costs relating to discount coupons.[3,4] A linear regression was calculated between the percentage of the advertising and promotional budget and the percentage of sales (market share) for each of three tar yield categories (3 mg tar or less, 4–6 mg tar, and 7–9 mg tar). The

regression analyses were limited to the years 1979 through 1981 because these were years in which promotional budgets were increasing each year for the three yield categories. Detailed data were not available from earlier years. Other patterns in the data in Table 1 are discussed.

A 0.4 to 0.5 per cent market share of this huge market is generally considered successful.[5,6] In 1979, a 1.0 per cent market share could supply just over 850,000 one pack-a-day smokers with cigarettes for one year; and a 1.0 per cent share of the promotional budget was worth $10.8 million. A difference of 1 percentage point in market share or promotional budget was considered substantial and worth discussing.

Results and Discussion

The regression results for 4–6 and 7–9 mg tar were so similar that a single regression is reported for the 4–9 category. Sales of 4–6 and 7–9 mg tar cigarettes were strongly related to the promotional expenditures (slope = 1.17, SE = .07), while the sales of 1–3 mg tar cigarettes were only weakly related to promotional costs (slope = 0.14, SE = .047) (see Figure 1). This supports the boundary model of smoking which argues that smokers may find a wide range of nicotine doses acceptable, provided that a minimum, "lower boundary" level of nicotine intake can be maintained.[1,7]

After the increase in promotion from 1979 to 1981, there was a leveling off for the 7–9 mg tar cigarettes, and a substantial drop in promotion of both the 4–6 and the 1–3 mg tar cigarettes (14 per cent and 64 per cent decrease); sales remained steady for the 4–6 mg tar cigarettes, but dropped for the 1–3 mg tar cigarettes (2 per cent increase vs 22 per cent decrease) (see Table 1). (The 1982 values for sales and advertising for 7–9 mg tar cigarettes do fall on the same regression line as for the earlier years.) Most of the sales of the 1–3 mg tar cigarettes may have been due to smokers temporarily trying these cigarettes rather than adopting them as their brand; hence when the promotion declined, the trial purchases declined. The 4–6 mg tar cigarettes may have been more likely to find consumers who adopted them as their brand, hence the steady sales when the promotion declined. There is also evidence for a sensible "tuning" of promotional costs and sales over the years. Those interested in making a profit cannot be expected to continue promoting products that are not selling. The historical pattern suggests that with promotion consumers can be drawn to brands in the 7–9 and even the 4–6 mg tar ranges, but this may be increasingly difficult for the kind of individuals (i.e., lower socioeconomic status, possibly more addicted) who remain as smokers in spite of years of pressure against smoking.[8]

In 1977, some health authorities thought that anti-cigarette legislation would be forthcoming to limit tar yields to a maximum of 15 mg (the FTC designation for "low-tar")[9]; and the president of one cigarette company suggested that market forces rather than legislation would "soon" bring about a 15 mg tar limit.[9] Currently, a 15 mg tar limit is far from a reality. The sales-weighted trend toward smoking lower and lower yield cigarettes has been flat since 1982.[10] In 1986, 47.4 per cent of the cigarettes sold in the United States delivered at least 16 mg tar.[4] Although there is dispute about the extent to which lower yield cigarettes are less hazardous than higher yield cigarettes, there are few who would argue that higher yield cigarettes are less hazardous.[11] Although the health benefits of such a market change are likely to be very small to individual smokers, they may yield worthwhile public health benefits.[11,12]

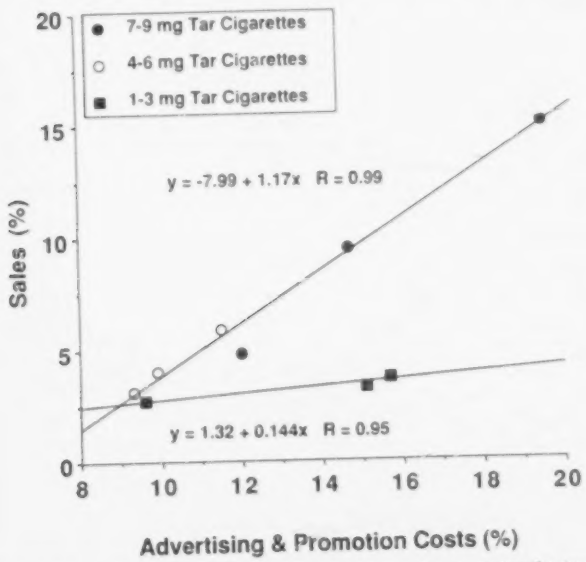

FIGURE 1—Percentage of sales of cigarettes in three low-tar categories (see insert) as a function of percentage of promotional/advertising budget for the years 1979, 1980, and 1981. For each tar category, the left-most point is 1979 and the right-most point is 1981. (Note that the abcissa is plotted from "8" and not zero.)

Accuracy of Recalled Smoking Data

ELIZABETH A. KRALL, PHD, ISABELLE VALADIAN, MD, JOHANNA T. DWYER, DSC, AND JANE GARDNER, DSC

Abstract: Validity of recalled cigarette data was assessed among 87 middle-aged adults by comparing recall to longitudinal records. Agreement on smoking status and amount smoked 20 years ago occurred for 87 per cent and 71 per cent of subjects, respectively. Corresponding proportions for 32-year recall were 84 per cent and 55 per cent. Gender did not influence recall accuracy. Ex-smokers tended to make the most errors. Accuracy of recalled smoking information 20 years ago was comparable to that of alcohol status and consumption frequency category. (*Am J Public Health* 1989; 79:200–206.)

Introduction

Information obtained by recall is vulnerable to numerous inaccuracies and biases; nevertheless, retrospective methods are commonly used to determine past exposure to such substances as tobacco and alcohol. Studies evaluating the accuracy of long-term recall (10 years or more) of smoking data are few.[1–3] Although faulty recall of prior smoking status was rare, more than half the respondents in one study incorrectly reported amounts smoked 15 years previously.[1] Exact agreement between recall of alcohol consumption frequency and that recorded 15 years before occurred for approximately half the respondents in a community study.[4] Overestimation of alcohol consumption has been noted.[5]

This paper examines the accuracy of retrospective smoking reports at two time points (20 and 32 years earlier) among a group of middle-aged men and women. Recall of smoking 20 years ago is compared to that of alcohol consumption at the same time point.

Methods

The participants were enrolled prenatally between the years 1930 and 1938 in a longitudinal study of health and development.[6] The original cohort (n=134) was drawn from middle-class, Caucasian families living in Boston. During childhood (until age 18), subjects were examined and interviewed annually. Further contact occurred in 1965 and 1984–85. At age 18 and 1965 interviews, smoking and dietary histories were obtained by use of standardized questionnaires.

Forty-three men and 52 women, the majority of whom resided in New England, participated in the 1984–85 follow-up. The mean educational level was 14 years, and ranged from 10th grade to professional degrees. Age ranged from 47 to 54 years.

Subjects completed self-administered questionnaires on which they recalled smoking status, number of cigarettes or packs per day, and consumption frequencies of beer, wine, and liquor approximately 32 years before (at age 18 follow-up) and 20 years before (in 1965), in that order. Recall calendars helped them focus on the appropriate time points. Current smoking status and amount smoked were also obtained. Two subjects who failed to finish the 1984–85 interview and six men who smoked only pipes or cigars were subsequently excluded from analyses.

Validity of retrospective smoking and alcohol reports was assessed by comparing them to data recorded at previous interviews. Actual and recalled cigarette doses were coded into four categories: none; <1 pack/day; 1–2 packs/day; or ≥2 packs/day. Conversion to categorical data was done because fractions of packs rather than number of cigarettes were most often reported. Actual and recalled weekly consumption frequencies of beer, wine, and liquor were summed and the totals recoded into four categories: none, <1 drink/day; 1–3 drinks/day; or ≥4 drinks/day. Proportions of subjects recalling an amount in a category consistent with recorded data were evaluated by kappa statistics[7] and differences between proportions by chi-square statistics.

Current smoking status definitions were based on 1984–85 reports. Current nonsmokers were subclassified into those who were nonsmokers both 20 and 32 years ago, and those who smoked at either earlier time point.

Results

The proportion of smokers in this group decreased from a maximum of 59 per cent 20 years earlier to 33 per cent at present; half the current smokers had reduced the number of cigarettes per day since they began smoking. In contrast, the proportion of alcohol users increased by 14 per cent during the same interval and mean consumption rose by three drinks per week.

Table 1 presents the agreement between recalled and historically recorded smoking status 20 and 32 years ago. The kappa statistics indicate better than chance agreement. There were no differences in accuracy by gender, current smoking status, or length of recall interval.

Amount smoked was recalled less accurately than smoking status (Table 2). Current smoking status, but not gender, influenced recall accuracy. A significantly smaller proportion of ex-smokers than both never-smokers or current smokers correctly recalled cigarette smoking level 20 years ago and 32 years ago. Even though recall was better than chance, a substantial proportion were misclassified by their retrospective reports. Further examination of these reports revealed that underestimation of amount (17 per cent for the 20-year and 37 per cent for the 32-year recall) was more common than overestimation (9 per cent and 6 per cent).

The proportions of respondents correctly reporting past smoking status (90 per cent) and cigarette dose (74 per cent) 20 years earlier were similar to those correctly reporting alcohol use status (86 per cent) and consumption frequency (61 per cent). Men and women reported equally well. Unlike smoking, however, underreports of alcohol consumption

level (1½ per cent) were less common than overreports (28 per cent).

Discussion

In the present investigation, we extended the length of recall of cigarette use beyond the 10–18 years reported by others.[1–3] Our findings are consistent with those previously cited. Recall of past smoking status was valid, but poor memory of quantitative detail such as cigarette dose, which is often of greater interest, led to frequent misclassification of prior consumption level, particularly by ex-smokers. The somewhat better recall of cigarette dose by these individuals compared to a previous study[1] may have been due to a higher proportion of never-smokers, whose recall was most accurate, or an effect of the life-long attention to and reporting of health-related information required of this cohort. Smoking and alcohol habits were remembered equally well.

Our data are also consistent with observations that current smoking or alcohol levels bias estimates of past use.[1,4,5] Present smoking levels were lower than those 20 years ago and retrospective estimates understated true past cigarette use. Overestimation of alcohol consumption by the recall method was observed in conjunction with an increased

prevalence of this practice. Alternatively, differences in social acceptability of the two practices may have influenced recall.

A limitation of this study and others with similar design[1–3] that makes it difficult to generalize to any smoking recall task is that subjects were asked to remember smoking habits at brief and specific time points. Continuous practices may be easier to remember, possibly making comprehensive smoking histories more accurate. This issue could be better resolved by administering retrospective smoking questionnaires to individuals whose smoking habits have been recorded prospectively at frequent intervals.

Validity of Telephone Surveys in Assessing Cigarette Smoking in Young Adults

RUSSELL V. LUEPKER, MD, UNTO E. PALLONEN, PHD, DAVID M. MURRAY, PHD, AND PHYLLIS L. PIRIE, PHD

Abstract: Self-reports of cigarette smoking in a sample of young adults, ages 17 to 21 (n = 359) obtained by telephone were validated by home interview and saliva cotinine measurement. While most subjects were in agreement for their reported behaviors, the telephone methodology underestimated cigarette smoking rates by 3 to 4 per cent. Reported quitting by telephone was an unstable category with 35 per cent of quitters reporting smoking on home interview. Reliance on telephone methods alone may underestimate smoking behavior. Validation of surveys, preferably by biochemical methods, is recommended. (*Am J Public Health* 1989; 79:202–204.)

Introduction

Telephone interviews have certain advantages relative to cost, convenience, and participation compared to face-to-face interviews. However, it is legitimate to question telephone methods for determining behaviors such as cigarette smoking, particularly in populations known to be likely to underreport—e.g., adolescents,[1] participants in cessation programs.[2] Information comparing telephone to face-to-face interview methods is limited but the results have not been reassuring. One repeatability study reported poor comparability in the number of cigarettes smoked per day, the age of quitting, and the age of initiating smoking among young Australian veterans (ages 29–39).[3] Massey, *et al*,* compared telephone and home interview methods finding 17–19 year-old males had a tendency in telephone interviews to underreport their current smoking and overreport quitting. Neither of these studies used biochemical measures to validate the smoking self-reports.

To better assess the reliability and validity of the telephone interview for cigarette smoking behavior among young adults, comparison was made to subsequent face-to-face interviews validated by saliva cotinine.[4,5] The results and the implications for survey data gathered by telephone methods are presented.

Methods

Subjects were young adults (ages 17 to 21) living in the Minneapolis-St. Paul metropolitan area and representing the classes of 1985 and 1986 from seven area high schools. They were interviewed by telephone between July 1, 1986 and June 30, 1987 to collect information on smoking attitudes and behavior. Participants were representative of a cohort of 7,124 adolescents followed annually to assess changes in smoking habits during young adulthood.[6]

Four groups (described below) were defined: non-smokers, smokers, and short- or long-term quitters. The sampling fraction for each group was based on estimates of their prevalence in the whole population to provide adequate sample size to detect meaningful differences between telephone and home interview responses: 14 per cent non-smokers, 20 per cent smokers, and 81 per cent quitters who resided in the metropolitan area. Sampling was random within each group. Subjects were invited for a home interview 11 to 31 days after telephone interview. Participants were paid $20 to answer an interviewer-administered questionnaire including the tobacco use questions asked by

telephone and to provide a saliva sample for cotinine analysis by gas chromatography.[7] Methods of saliva sample collection are described elsewhere.[8]

The four groups according to their cigarette smoking status at the phone interview were: *Non-smokers* were those who did not smoke at the time of the interview, had smoked less than 100 cigarettes during their lifetime, or had quit smoking more than one year previously. *Smokers* were those currently smoking who had smoked more than 100 cigarettes in their lifetime. *Short-term quitters* had stopped smoking during the 60 days before the telephone interview. *Long-term quitters* had quit smoking more than 60 days but less than 365 days.

Results

Of 6,712 subjects surveyed by phone (participation = 94.2 per cent; 6,712/7,124), 729 were asked to participate in the home interview, and 587 complied (80 per cent). As shown in Table 1, non-smokers not in school and male quitters were somewhat less likely to participate in the home interview. This may be due partly to the requirement of still living in the metropolitan area; males and university students are more likely to out-migrate. The data presented here include only 359 of the 587; the difference is due to inaccurate cotinine measurements caused by laboratory equipment failure during the first part of the study. Subjects with these samples did not differ from those in the analyses in reported smoking habits.

Comparison of the telephone interview with the home interview (Table 2) shows that agreement was high among non-smokers (95 per cent), and smokers (97 per cent). The lowest agreement was found among those calling themselves short-term quitters during telephone interview. On the home interview, many subsequently reported smoking (59 per cent). A smaller but substantial proportion of those reporting by telephone to be long-term quitters also subsequently reported smoking on the home interview (28 per cent).

Table 3 compares self-reported smoking by telephone and home interview with saliva cotinine. Previous studies in this laboratory with known smokers and non-smokers suggest that 20 ng/ml provides good sensitivity and specificity for detecting regular cigarette use in this age group (data available from first author). Individuals who used smokeless tobacco one week prior to the home interview were excluded. Compared to the telephone interview, most reported non-smokers (96 per cent) had cotinine levels less than 20 ng/ml while most smokers (93 per cent) had cotinines above 20 ng/ml. Short-term quitters, by telephone interview, were likely to have elevated cotinine levels (54 per cent), as were reported long-term quitters (27 per cent).

TABLE 1—Demographic Characteristics of the Home Visit Participants and the Total Sample

Non-smokers		Smokers		Quitters	
Home	All	Home	All	Home	All
Average Age (years)					
19.00	18.94	19.01	18.93	18.96	18.98
Gender (% Male)					
50.56	52.68	44.10	47.50	45.71	51.05
% Graduated from High School					
97.50	96.44	80.51	75.15	88.00	85.25
% Current Student					
45.83	55.45	30.77	28.05	38.86	41.22

TABLE 2—Smoking History: Telephone vs Home Interview

	Home interview				
Telephone Interview	Non-smoker	Smoker	Short-term Quitter	Long-term Quitter	Total
Non-smoker	175	5	1	4	185
Smoker	1	87	2	0	90
Short-term Quitter	1	10	4	2	17
Long-term Quitter	9	19	2	37	67
Total	186	121	9	43	359

The home interview also showed high concordance between cotinine and smoking status in smokers and non-smokers; however, the home interview also showed higher concordance with cotinine for short-term quitters (100 per cent) and long-term quitters (93 per cent).

Table 4 extrapolates the marginal prevalence rates presented in Table 2 to the entire cohort of 6,712 subjects based on the sampling fractions used in this study. As is apparent, prevalence based on the home interview suggests a higher rate of smoking and a lower rate of non-smoking than do the rates based on the telephone interview; the prevalence of quitting is relatively unaffected by the source of the data. McNemar's test for symmetry confirmed that these differences were greater than would be expected by chance.

Discussion

These data suggest that telephone survey methods underestimate smoking rates and overestimate non-smoking. Both long- and short-term quitting by telephone interview, while constant in size, are unstable categories with subjects leaving and entering in the short interval between surveys. Extrapolating the home survey data to the entire population as seen in Table 4 increases smoking rates by 3.1 per cent (24.2 to 27.3 per cent). A portion of this derives from a few individuals who described themselves as non-smokers on the telephone but reported smoking at home interview. These are likely deceivers. The remainder of the smoking increase results from short- and long-term quitters on the telephone who reported regular smoking at home interview. This may be due to real relapse but may also be underreporting on the telephone.

This study observed a constant proportion of short- and long-term quitters. However, this category was highly unstable with a substantial portion of long- and short-term quitters on the telephone reporting smoking on home inter-

TABLE 3—Distribution of Self-reported Smoking at the Telephone and Home Interviews as a Function of Cotinine Level

	Smoking History: Telephone vs Saliva Cotinine

Home interview	67.3	27.3	5.5

view. This underreporting of smoking was balanced by individuals who reported non-smoking on the telephone but describe themselves as quitters at home.

The use of cotinine as a validating tool has two effects. First, chemical measurement tends to increase accurate reporting of smoking on interview.[1] In addition, it can appropriately classify individuals who continue to underreport even on direct interview. The use of cotinine measurement adds further to the smoker category. Smoking prevalence, as defined by cotinine, would be 28.6 per cent, or a 1.3 per cent increase over the home interview level.

In summary, telephone interviews for smoking behavior may lead to 3–4 per cent underreporting of smoking behavior. Quitting is an unstable category because of relapse and misreporting. These factors need to be considered when performing telephone interviews for smoking or other proscribed behaviors. Wherever possible, validation, preferably by biochemical measures, should be included to accurately estimate prevalence.

ACKNOWLEDGMENTS

Patient Literacy and the Readability of Smoking Education Literature

CATHY D. MEADE, RN, PHD, AND JAMES C. BYRD, MD, MPH

Abstract: This study was designed to determine if primary care clinic patients read at a level congruent to the reading grade level of available smoking literature. Reading estimates of smoking education literature (N = 49) ranged from grade 3 to college level (median = 9.5). Reading skills of 258 smoking patients were estimated by reported years of schooling (median = 10), and by scores on the Wide-Range Achievement Test (median = 6). A serious disparity existed between the reading estimates of smoking education literature and the literacy skills of patients in our sample. (*Am J Public Health* 1989; 79:204–206.)

Introduction

Smoking is the cause of 350,000 premature deaths a year in the United States.[1,2] Smoking educational literature is commonly distributed to reinforce patient education and extend verbal instructions regarding smoking cessation.[3–7] Printed materials are suitable only when they can be read and comprehended.[8] There is strong evidence that a disparity exists between reading levels of written health materials and reading skills of target populations.[9–16]

Readability formulas are designed to make quick assessments of the readability of printed text.[17] Developers of written materials must also consider such elements as content, format, technical accuracy, organization, reader interest, and motivation.[8,18,19]

Educational level is often the only indicator used by practitioners to evaluate patient's comprehension skills. It has been suggested that reading skills may be two or more grade levels lower than stated educational levels.[10,11,14,15,20] Informal cues which may indicate that patients have low reading skills include blaming their inability to read on forgotten glasses or exhibiting facial signs of frustration while reading a passage.[21] More formal methods of estimating reading skills involve administering the CLOZE procedure[22,23] or the Wide-Range Achievement Test (WRAT).[24]

We compared reading levels of smoking educational materials with the reading skills of smokers.

Methods

Sources of written smoking educational materials (N = 49) were collected from organizations that supported smoking cessation activities: American Heart Association (N = 7), American Lung Association (N = 14), American Cancer Society (N = 7), government agencies (N = 12), and private

organizations (N = 9). Three one-hundred word passages were randomly selected from each booklet. Estimates of the readability of each booklet were calculated by the Minnesota Interactive Readability Approximation Microcomputer Program (MNIRAP), a text analysis program intended to predict reading level estimates of educational materials. A computerized approach was selected over manual calculations of reading estimates of the smoking education booklets to increase the reliability of the results and decrease human error. The following formulas are calculated from the program: Dale-Chall, Raygor, Fry, Flesch, Gunning-FOG, and SMOG.[25]

The patient sample consisted of 258 subjects from the Primary Care Clinic of the Milwaukee County Medical Complex (a public hospital facility) who were participating in a smoking cessation program. All subjects were 18 years of age or older, English speaking, English reading, and had corrected vision that allowed for ease of reading. Each participant was asked to state their completed years of schooling and were then administered the WRAT Level 2. The WRAT consists of a graded list of words that yields a word-recognition grade level score. It is easily administered, scored in a manner of minutes, produces highly reliable and valid scores, and has been used in a variety of clinical settings.[10,11,14,24]

Results

The readability estimates of the 49 smoking education booklets ranged from grade 3 to scientific/professional level, with the majority of booklets written above grade 9. Table 1 illustrates the range of readability levels for a sample of five smoking booklets. Pearson Product Moment Correlations revealed that the formulas were positively and highly correlated with each other and ranged from (r = 0.75, 95 per cent CI: .59, .86 to r = 0.99, 95 per cent CI: .98, 1.0). Due to the strong correlations between formulas, one readability formula (SMOG) was selected for use as a comparison for the study results. This formula was selected because it is used widely in analyzing health literature and is a quick and easy method for estimating readability if a microcomputer program is unavailable.[10,14,18,26] According to the SMOG formula, there were 10 booklets written at grades 6 to 8.9, 27 booklets written at grades 9 to 11.9, and 12 booklets written at grade 12 and greater level. The mean reading level of the booklets according to the SMOG was grade 10.5 with 80 per cent of booklets written at grade 9 and greater (details of analyses available on request from author). Chi-square analyses revealed that there was no significant difference between the mean level of readability of the booklets obtained from the various public and private organizations.

The reported level of education of the subjects ranged from no schooling to college level with a median level of grade 10. Reading ability as measured by scores on the WRAT ranged from less than grade 3 to above grade 12 with a median level of grade 6. There was a moderately positive correlation between reported years of schooling and WRAT scores (r = 0.5550, 95 per cent CI: .47, .63). The mean difference between educational grade level and WRAT score was 3.8 grades which was statistically significant (t = 19.226, 95 per cent CI: 3.45, 4.21). Of the 90 subjects (35 per cent) who stated that they had completed high school, only 45 (18 per cent) demonstrated this level on objective testing. Although 77 per cent (N = 178) of the patients had a WRAT score of less than grade 9, only 23 per cent (N = 59) had stated educational levels less than grade 9. Fifty-four per cent of the subjects (N = 119) had reading levels (WRAT scores) less than grade 6.

A serious disparity existed between reading levels of patients and reading estimates of smoking literature (Figure 1).

Discussion

We have identified an incongruence between the reading level of written smoking educational materials and the reading skills of patients in our primary care clinic. Our results support the finding that the mean grade level of patient education booklets often ranges from grade nine to eleven, and are written at levels greater than the reading skills of the target population.[9,10,14–16,27,28] Results also indicated that agencies committed to smoking cessation activities write their publications at similar reading levels (grades 9–11).

Readability, predicted by a readability formula, is a necessary first step in the development of smoking educational materials. It offers an objective measure of text difficulty. Patient motivation, type, size, format, or use of graphics must also be considered.[29–31] Readability formulas do not take into account the fact that some longer words may increase clarity and be more familiar to the smoker e.g., cigarette and nicotine. Such factors must be considered when developing written texts for smoking patients.

Users of readability formulas need to consider that formulas have been validated in previous studies, but not on health care populations.[19,25,32–38] The scores obtained by the various methods for a given booklet may differ because of the measures used as predictors and the criterion by which the methods were validated. Future research needs to be directed to better identify if the SMOG is the most appropriate formula for estimating readability of health materials.

Years of schooling was not found to be a reliable predictor of reading ability. Other informal and formal indicators of reading skill must be used by practitioners to determine the patient's literacy skills. Incorporation of an objective test such as the WRAT is recommended for

inclusion in a patient assessment. Patients in our setting did not appear threatened or frustrated by use of this instrument even when their reading skills approached illiteracy.

The median educational level of our patients was grade 10 which is lower than national statistics which identify grade 12.6 as the median educational level.[39] Individuals with less than a fifth grade reading ability (44 per cent of our sample) can be termed "illiterate",[40] and may not benefit from written materials. Other methods of smoking cessation education need to be explored and evaluated. These include use of flip charts, videotapes, audiotapes, picture books, or computer-assisted instruction.[20,41]

Evaluating both the readability of the smoking educational literature and the comprehension levels of patients allows practitioners to determine whether health information is compatible with the reading skills of their patients. This philosophy can help create positive smoking health messages that patients want to read, can read, and can understand.[8,19,26]

Age of Initiation and Switching Patterns between Smokeless Tobacco and Cigarettes among College Students in the United States

ELBERT D. GLOVER, PHD, MOLLY LAFLIN, PHD, AND STEVEN W. EDWARDS, PHD

Abstract: A stratified, random, multi-stage, cluster sample of physical activity classes among 72 colleges and universities throughout the United States yielded 5,894 usable responses (males=2,888); (females=3,006). Twenty-three per cent of the students who began smoking before the age of 10 were current smokers, while 61 per cent of those who began using smokeless tobacco before the age of 10 were current smokeless tobacco users. College students were more likely to switch from smokeless tobacco to cigarettes than from smoking cigarettes to smokeless tobacco. (*Am J Public Health* 1989; 79:207–208.)

Introduction

A great deal of speculation has been focused on the age at which smokeless tobacco users initiate the habit and whether these young dippers and chewers eventually switch to cigarettes or whether the reverse pattern holds: i.e., cigarette smokers switching to smokeless tobacco. In oral testimony before the National Consensus Development Conference, Christen[1] and Hunter[2] testified that young people initiate smokeless tobacco and then switch to cigarette smoking due to the fact that, as users become older, smokeless tobacco becomes more socially unacceptable. Conversely, Glover[3] testified that due to the tremendous publicity surrounding the health hazards of smoking cigarettes, youthful smokers view smokeless tobacco as a safe alternative to cigarettes, and consequently choose to become dippers or chewers after initiating tobacco behavior with cigarettes.

The answers to these questions will require a longitudinal study. However, because the health consequences of tobacco (smoking or smokeless) use are profound, the following national collegiate cross-sectional study using retrospective questions was undertaken.

Methods

Students at colleges and universities in the United States enrolling 2,000 or more undergraduates were the focus of this study. The US was stratified geographically into eight regions, with one state from each region randomly selected to represent that region:

Central: Ohio
South Central: Oklahoma
North Central: Minnesota
Rocky Mountain: Colorado
Southwest: Arizona
Northwest: Oregon
Northeast: Connecticut
Southeast: South Carolina

Thereafter, all colleges and universities in the eight states which met enrollment requirements of 2,000 or more students were contacted requesting their participation. Of the 109 schools contacted, 72 (66 per cent) chose to participate, five declined, two could not administer the questionnaire within the prescribed time, and 30 did not respond to repeated contacts.

In April 1986, at each participating college or university, random physical education activity classes were sampled; irrespective of their major, students were required to take activity classes in 67 of 72 colleges. The activity classes were randomly drawn from the most active classes (weight lifting) to the least active (bowling). The sample closely matched race and gender enrollments of each university population. The chairperson at each of the 72 participating schools was asked to survey approximately 100 subjects in a cluster of two to five classes. Several schools returned less than the 100 surveys requested, and 562 surveys were eliminated for failing to follow instructions or omitting portions of the survey.

The operational definitions for regular users were self-reports of current users using half a pouch (chewers), half a can (dippers), or half a pack (cigarettes) for more than three months. Age of initiation was defined as first age of regular use and not first experimentation.

The survey instrument, a 42-item questionnaire, contained a section soliciting demographic information followed by questions on cigarette smoking and smokeless tobacco use.[4] The data were checked and analyzed with the Statistical Analysis System (SAS), Version 5.

Results

The sample consisted of approximately equal percentages of male (49 per cent; n=2,888) and female (51 per cent; n=3,006) students. Mean age was 20.8 years. Eighty-six per cent (n=5,069) were White; there were 413 Blacks (7 per cent). Approximately one-third of the subjects were freshmen with decreasing numbers of sophomores, juniors, seniors, and graduate students. One-third of the subjects came from cities with populations greater than 50,000, approximately one-fourth from cities of 30,000-50,000, and the rest in decreasing order were from smaller towns, and rural (<5,000) areas.

The overall prevalence of cigarette smoking was 14 per cent and for smokeless tobacco products 12 per cent. Females were more likely to smoke than males (16 per cent vs 13 per cent) and males were more likely to use smokeless tobacco (22 per cent vs 2 per cent). The age of initiation of tobacco use among college students did not vary a great deal by tobacco type (cigarette vs smokeless products).

Data from questions regarding the age at which college students initiated cigarettes or smokeless tobacco and whether they currently used tobacco products revealed that those who initiated cigarette smoking at an early age were less likely to be current users than early age initiators of smokeless tobacco. In contrast, there was a strong association between age of initiating smokeless tobacco and current

TABLE 1—Age of Initiation of Tobacco Use vs Current Use of Tobacco by Gender and Tobacco Type

smoking. Of those who initiated either habit, most began at age 16 or older (Table 1).

While most current smokeless tobacco users do not smoke, those who began using smokeless tobacco prior to the age of 13 were proportionately more likely to be current smokers than those who did so at later ages (Table 2).

Most college students who smoked, did not use smokeless tobacco; however, the likelihood of smokers starting to use smokeless tobacco decreased substantially for those students who began smoking at ages 13-15 and 16 and older when compared with those who began smoking before the age of 10 or between the ages of 10 and 12 (Table 3).

Eighteen per cent of those who had started at any age had also used smokeless tobacco. Twenty-eight per cent of those who had ever used smokeless tobacco had also smoked cigarettes regularly. Among current smokers, 15 per cent occasionally used smokeless tobacco, and among current users of smokeless tobacco, 18 per cent occasionally smoked.

Discussion

In our survey the age of initiating tobacco use among college students did not vary a great deal by tobacco type (smokeless or smoking), contrary to two statewide studies of students grades 3 through 12 who started to use smokeless tobacco at earlier ages than cigarettes.[4,5] Presumably, the sudden upswing in popularity of smokeless tobacco over the past few years accounts for the difference. As the cohort of young initiators currently in elementary and secondary schools reach college level, the reported age of initiation may change. However, since educational level influences smoking, perhaps these two distinct populations (college vs secondary or elementary) will continue to show differing patterns of use regarding smokeless tobacco.

The smoking data on age of initiation of cigarettes and its relation to current smoking were also contrary to previous research which showed that smokers who initiated smoking earlier were more likely to continue smoking.[6] There is no ready explanation for this discrepancy. However, at the time of this data collection smokeless tobacco was very popular and this, as well as the nature of our sample, may have influenced our findings.

The 1986 Surgeon General's Report[7] and the 1986 Consensus Development Conference[8] were concerned that youngsters were turning to snuff and chewing tobacco as an alternative to cigarette smoking. While this may hold true for younger age groups, our data from college students suggest the switch was from smokeless tobacco to cigarettes. Moreover, most of the persons we surveyed will secure white collar jobs, where smokeless tobacco is not socially acceptable. No effort was made to validate self-reports; since we were interested in switching patterns, validating self-reports may have been less important.

Public Health Then and Now

The Sociologic Context of Occupational Health in South Africa

JONATHAN E. MYERS, BSc, MBChB, DTM&H, MD AND IAN MACUN, BA

Abstract: The early history of the occupational health system in South Africa is outlined up to the early 1970s which mark a political and social transition in the society. Relevant demographic and social data are provided, and the roles and mutual relations of capital, labor, state, and academic sectors are discussed. During the past 15 years there has been heightened occupational health activity. Major legislative activity has included several commissions, the promulgation of new laws and regulations governing the workplace, and deregulatory measures in a contradictory mix. Conflictual relations between social forces are illustrated by two examples involving the introduction of safety representatives in the workplace, and compensation for occupational lung disease. The implications of wider political and economic realities are analyzed, and current and probable future trends in the evolution of the occupational health system are identified. (*Am J Public Health* 1989; 79:213–221).

Introduction

This paper seeks to present an account of the occupational health situation in South Africa. Part I is an historical documentation of the evolution of the occupational health system, covering both political and legislative aspects up until the early 1970s, which mark a political and social transition in the society; Part II consists of a demographic and sociologic profile of the society in relation to occupational health; Part III deals with the relatively underdeveloped occupational health infrastructure in South Africa.

Part IV is the core of the article. Since the 1970s there has been heightened occupational health activity, and it is the social dynamics of this most recent period that are of concern. Legislative activity has included several commissions and the promulgation of new laws and regulations governing the workplace. Relations between management, labor, and the state have expressed both inequalities of power and conflicts of interest with regard to the generation and implementation of new legislation. Wider political and economic realities have also had serious implications for health and safety. Recent events are reviewed with the purpose of identifying current and probable future trends in the evolution of occupational health activities.

I: An Historical Overview

Sociopolitical Factors

The history of South Africa is steeped in racism. This has affected all aspects of the body politic, and underlies the development of the occupational health system.

Industrial development began at the end of the 19th century with the discovery of diamonds and gold. The mining industry brought with it new patterns of industrial and political relations in which White mine owners, White skilled mine workers, and both Black and White unskilled mine workers were thrown together in a situation fraught with potential conflict and compounded by language-group hostilities among the Whites. Craft-based unions organized by White workers excluded Blacks on grounds of skill and race.

Persistent attempts by management to eliminate mining skills and to replace White with cheaper Black labor together with poor working and health conditions on the mines[1] led to a period of sustained conflict in the first two decades of the 20th century, culminating in an unsuccessful insurrection by White miners in 1922. The ruling party which supported the interests of mine owners was replaced shortly thereafter by a coalition of agrarian-based Afrikaner nationalist and White labor parties. Black South Africans were consequently excluded not only from the political structures of government but also from legal status as workers and from access to trade unions and industrial bargaining structures. This was the mechanism whereby the monopoly rights of Whites over skilled trades in both mining and non-mining industry were entrenched.[2]

A new wave of mainly Black trade unionism occurred during World War II when industry was highly dependent on Black labor due to the development of secondary industry stimulated by the war economy. This period was associated with a significant updating of occupational health and compensation legislation. However, in the 1950s and 1960s, Black labor demands were suppressed along with the wider political demands of Black South Africans by the enforcement of apartheid under the nationalist government that came to power in 1948.

The development of occupational health in South Africa has always been prompted by labor activity. Organized White labor succeeded in obtaining many concessions from capital such as preventive legislative and compensation legislation

for miners' phthisis and work-related accidents. Compensation benefits for pneumoconiosis among White mine workers were in advance of conditions enjoyed by workers in the developed countries of Europe and North America as far back as 1956 (The Pneumoconiosis Act, 57 of 1956). After separate but parallel struggles over health issues, Black workers succeeded in obtaining some coverage, although benefits were invariably racially discriminatory.

The role of production workers of different color changed profoundly over time. Most White workers took on supervisory and managerial roles which distanced them socially from Black production workers as well as from exposure to production hazards. White workers' racism and the incorporation of White labor unions into segregated state industrial relations structures led to the emergence of White-dominated or White-exclusivist trade union federations with a bureaucratic character.[3-5] These trade unions have often obstructed Black labor organization; they have tended to side with management or the state when direct political repression has been directed at democratic non-racial unions. To some extent, because of their experience with these organizations, Black workers have tended to develop a negative view of trade unions.

Legislation

South African occupational health legislation has generally followed two parallel tracks, one covering the mining industry, and the other dealing with non-mining industry, commerce and services.

Various laws relating to mining health and safety preceded the formation of the Union of South Africa in 1910. In 1901 the Government Mining Engineer in the Transvaal reported high mortality rates from miners' phthisis (a combination of tuberculosis and silicosis). This was followed by the first Commission of Inquiry into Phthisis in 1902, and three years later by the first mining regulations created to abate the dust hazard. The regulations were not particularly effective, and another commission, the Mining Regulations Commission of 1907, was set up to investigate dust control. The Commission's report in 1910 showed that the mortality of White miners was six times higher than that for adult males on the Witwatersrand. At this time small *ex gratia* payments were made by the mining companies to widows of victims of miners' phthisis.

The Colonial laws that existed prior to Union were consolidated into the Mines and Works Act, 12 of 1911, which was intended to provide for preventive measures and the protection of the health and safety of mine workers. The Act related mainly to the control of machinery. A further commission of medical practitioners was established to look into miners' phthisis and tuberculosis and to make recommendations for compensation. This resulted in the Miners' Phthisis Act of 1911 which introduced compulsory compensation for phthisis. These two Acts led, after various commissions and amendments, to the two main Acts currently in operation—the Mines and Works Act, 27 of 1956, and the Occupational Diseases in Mines and Works Act, 78 of 1973. These Acts provide for the control of the work environment on the mines, for risk or fitness examinations relating to miners' fitness for underground work, and for benefit examinations for occupational disease compensation.

Outside of the mining industry, the Workmen's Compensation Act No 25 of 1914 and an amendment of 1917 provided the first coverage for industrial accidents and occupational diseases, respectively. Disease had to be present along with disablement, and had to be causally related to work. Posthumous benefits were available only if death was caused by the occupational disease. Cyanide rash, lead and mercury poisoning were the three occupational diseases recognized and they were handled administratively as if they were accidents. These were augmented by ankylostomiasis in 1934, and by 1941, 15 occupational diseases including silicosis were scheduled as occupational diseases.

The first Factories Act was passed in 1918, and from 1924 industry was administered by the Department of Labor. Prior to this the mines and industry had been jointly administered by the Department of Mines and Industry. Limited coverage for white collar workers in offices was provided by the Shops and Offices Act, 41 of 1939. The new Factories, Machinery and Building Work Act, 22 of 1941, replaced the outdated 1918 law; it laid down basic conditions such as hours of work and regulations pertaining to the control of machinery. For the first time a Factories Inspectorate was constituted within the Department of Labor, with duties to inspect workplaces and investigate reportable accidents.

In 1958, the Minister of Labor appointed a departmental committee to investigate and make recommendations on the incidence of occupational diseases. The committee reported back in 1963 providing evidence of widespread occupational disease in South African industry, but the report did not result in any substantial preventive or compensation measures.

The Shops and Offices Amendment Act, 75 of 1964, introduced new health and safety-related protective measures relating to hours of work and other conditions of employment for white collar workers in shops and offices. The Factories Act was amended again in 1967 and some general health regulations were introduced but, with the exception of regulations relating to noise control, no regulations specifically dealing with occupational hazards were promulgated until the mid 1980s.

II: Demographic and Social Profile

Population

South Africa has a population of over 30 million which is divided by law into the following racial categories: Black Africans, people of mixed racial descent, Asians, and Whites (Table 1). The African segment is by far the largest, comprising about 80 per cent of the total population.[6] The social class breakdown demonstrates that the Black African population consists mainly of unskilled and semi-skilled workers, and the White population mainly of white collar and managerial personnel, while the Asian and mixed-race populations fall somewhere in between—closer to the Black African group than the White group[7] (Table 2).

A high proportion of the African workforce are migrant workers who commute back and forth from rural dormitory areas in the interior. These rural reserves were created by the 1917 Land Act which allocated a small proportion of South Africa's land for the majority African population. In recent years some of the reserves have been designated "independent" ethnic or tribal states by the South African government in terms of its Bantustan policy. These areas have no economic viability apart from their relationship to South Africa. No African peasantry remains after a century of migrant labor, dependence on earnings in the wage economy of White South Africa, overcrowding of the reserve areas, generalized impoverishment, and high unemployment.

TABLE 1—Demographic Profile of South Africa: Population Estimates 1986 (in millions)

Demographics	Population in millions (%)

Capital

South Africa is a relatively well-developed capitalist country. There is an important locally based large capital sector, in addition to the presence of foreign capital. These sectors tend to favor independent labor organization and more representative political dispensations. There are also significant medium and small capital sectors, and a large state production sector which is conservative in its labor policies. More recently there has been a concerted attempt to encourage the development of an informal sector (family production and trading) and a small capital sector; this attempt takes the ideological and political form of a campaign to deregulate the economy.

Labor

By third world standards, South Africa has a large working class, comprising about one-third of the total population. After a 10-year lull, the Black working class manifested its presence again in the early 1970s through a series of strikes involving large numbers of workers in important industrial centers of the country. This heralded the beginning of today's independent trade union movement.[8]

Trade unions—independent of the management and racially based structures characteristic of the state industrial relations system prior to the 1980s—now have a national presence in most industries. The two national federations are the Congress of South African Trade Unions (COSATU) and the National Council of Trade Unions (NACTU). Estimated membership figures are given in Table 1. There are approximately one million members of the independent trade union movement,[9,10] about 10 per cent of an economically active population of 10,000,000. Although this represents only a modest proportion of the total workforce, membership has increased rapidly in recent years, and is relatively strong in some of the most crucial sectors such as mining, metals, and chemicals (Table 1). The old White-dominated Trade Union Council of South Africa disbanded at the end of 1986 after experiencing rapidly declining membership in the 1980s due to major splits and desertions by component trade unions with large numbers of Black members. As Table 2 indicates, although there are trade unions for the small number of residual "White workers," this social category hardly exists.

Because the independent workers' movement has grown from below in open conflict with state, capital and race-segregated or White-dominated trade unions, there have been opportunities for grassroots or rank and file organization to develop at shop floor level, and the possibility of workers being incorporated into unrepresentative joint structures with representatives of the state and management (such as joint health and safety committees) has been minimal. By contrast with other African countries whose national trade union bodies have appeared within a year or two of independence in situations of little rank and file organization in the factories, it took 12 years of organization to establish COSATU in 1985 by which time factory organization was fairly solidly based.[11] Despite the severe economic effects of the recession, disinvestment, massive retrenchments of workers in most industries, and political repression since 1985, much of which has been aimed at the independent trade unions and COSATU, there has been an exponential increase in membership.[9] Health and safety issues have been successfully negotiated with managements.[12–14]

Other Black Social Groupings

Although there is no longer a significant self-supporting peasantry in the rural areas, a dormitory working class exists; resettled urban unemployed, ill, and old workers and women and children live in rural "towns" with no access to the means of subsistence production. There is also a significant

TABLE 2—Percentage Composition of the South African Population by Race and Social Class, 1969–77

and fast-growing middle class consisting of white collar workers, professionals, government employees and functionaries, small-business operators, and small traders. This process of class transformation is being actively assisted by the state and capital, especially large capital.

The State

Since the implementation of the new constitution in 1984, White, mixed-race, and Indian South Africans have been separately enfranchised in racially exclusive representative bodies. The majority of workers, Black Africans, are not enfranchised. As Black workers generally perceive the state to be hostile to their interests, it has been very difficult for the state to incorporate their organizations. Lack of political representation has in fact been an important stimulus for the Black working class to develop alternative channels of political representation through their trade unions by winning respect from management, putting forward their ideas and demands, and by gaining rights and conditions of work exceeding those provided for in the law.

Before 1979 the state followed a course of suppression of Black labor organization. The 1979 Wiehahn Commission elaborated a more sophisticated and systematic attempt by the state to control the independent trade union movement and to extend "normal" industrial relations structures in the hope that this would lead to the incorporation and containment of Black trade unions and labor militancy.[15,16] During the period 1979 to 1984 there were protracted conflicts between organized labor and the state[17] around such issues as the registration of trade unions, state control and incorporation into the state industrial council system. The state lost ground in these conflicts: restrictive race-segregation conditions had to be dropped from registration criteria for unions, and independent unions have generally been able to join industrial councils on their own terms and utilize their status and presence to the advantage of their members, while reserving their right of non-participation.

It may be argued that a combination of antagonism between the state and Black workers and the availability of occupational health benefits won historically by white labor have allowed the independent trade union movement to take advantage of such concessions without being easily subject to domination or incorporation.

III: The Occupational Health Infrastructure

The State Sector

The Medical Bureau for Occupational Diseases in Johannesburg operates a clinic where it executes its statutory duties under the Occupational Diseases in Mines and Works Act, 78 of 1973, relating to fitness and benefit certification examinations for White miners. Some epidemiological research is also conducted, and this has increased in recent years. The Bureau certifies Black miners with occupational diseases on the basis of their medical records and findings that are forwarded to it by local doctors on the mines, but Blacks are not examined on the premises. The Bureau is also the main medical certifying authority recognized by the Workmen's Compensation Commissioner for cases of occupational disease falling under the Workmen's Compensation Act, 30 of 1941.

The National Center for Occupational Health in Johannesburg runs a clinic where workers from non-mining industry who are suspected of having occupational diseases may be evaluated. This clinic does not have statutory functions like its counterpart at the Medical Bureau, and access to the clinic is not racially restricted. A combined panel of doctors from the Center and the Bureau evaluate cases seen at the

Center's clinic for purposes of certification; these certifications are also recognized by the Workmen's Compensation Commissioner. The Center is involved in basic and applied research into occupational medicine, industrial hygiene, pathology and toxicology, and has a well-equipped library which provides a national information service.

The nationwide National Occupational Safety Association is financed out of the Accident Fund established under the Workmen's Compensation Act. It is involved in voluntary safety audits of industrial firms and in providing information and educational activities related, until very recently, only to occupational accidents. Since the passage of the Machinery and Occupational Safety Act there has been a move to expand its educational activities to encompass occupational disease prevention.

The Corporate Sector

A substantial network of health services, consisting of hospital and general practitioner facilities, is associated with the mining houses. From an occupational health perspective, these services are geared mainly to emergency general health problems and occupational accidents and their sequelae.

The non-mining industry has a very poor record of occupational health services. A survey of occupational health services in the Greater Cape Town area found a low percentage (12.9 per cent) of workplaces with any health service at all (the lowest level of service was a part-time nurse).[18] A similar percentage was found in Germiston, which is one of the most heavily industrialized areas in the country.[19]

The Academic Sector

Occupational health is a neglected area within the medical schools. There is little time devoted to it in the undergraduate curriculum and as yet it is not a registered specialty. Departments of Community Health at several universities, principally the Afrikaans-language universities, have been active in the area for many years, and part-time postgraduate diplomas in occupational health are available at the Universities of Witwatersrand (in conjunction with the National Center for Occupational Health), Cape Town, Stellenbosch, and Pretoria. At Stellenbosch the medical school runs a rehabilitation clinic, and at Cape Town the medical school has a respiratory clinic for occupational diseases.

The Departments of Sociology at the Universities of Cape Town and Durban have research groups active in occupational health research, education, and consultancy. These are the Industrial Health Research Group and the Industrial Health Unit, respectively.

There is no university level industrial hygiene or environmental engineering training in the country. Industrial hygiene is currently part of the health sciences curriculum at technical colleges in major urban centers where diplomas in health inspection are offered.

Independent Service Organizations

The Work Information Group in Johannesburg and the Industrial Health and Safety Education Project in East London are active in occupational health research, information, and education.

The Trade Union Sector

Several of the independent trade unions have been active in health and safety. This activity has taken the form of union-run clinics (Food and Allied Workers Union and the Southern Natal branch of COSATU; health and safety departments and health and safety officers (National Union of Mineworkers); union medical officers (Food and Mineworkers unions); health and safety organizational structures such as shop stewards committees or safety representatives, health and safety educational activities for union safety personnel, and negotiated health and safety agreements conferring rights of access to health and hazard data. Unions are increasingly involved in direct and commissioned industrial hygiene and occupational health research activities and provide input to the government Department of Manpower on proposed health and safety legislation and regulation. Labor has drawn upon the resources of the various sociology departments and other independent organizations in many of these activities.

Occupational Epidemiologic Research

There is little reliable information about the extent of occupational disease in South African industry. Nationwide statistics are hard to obtain and the quality of available mortality and morbidity data for African workers cannot support meaningful epidemiologic studies.[20] Some statistics of variable quality for the mines are published by the Medical Bureau. The Workmen's Compensation Commissioner does not publish any data on occupational disease. Data are available for occupational accidents and show high mortality and morbidity, especially on the mines. The profiles of the older occupational diseases like pneumoconioses and metal poisoning have been documented by government sources as being high.[21] Newer occupational diseases like cancer, neurological damage, and musculo-skeletal conditions arising from chemical, solvent, and radiation exposures and poor workplace design are as yet undocumented and unstudied.

Historically occupational epidemiologic activity in South Africa has been linked to health problems associated with mining and, with a few notable exceptions, has related to dust-induced occupational diseases. Studies, not often published, have mostly originated in the statutory bodies (the Bureau and the Center). The bulk of published material has been in the form of case reports, pathology studies, and collections of statutory data with few prevalence or incidence studies. They have also been based mainly on data for White workers who constitute a very small and relatively unexposed section of the workforce especially in the mining industry.

The output of research from universities and corporations has been low, despite the existence of collections of routine data, particularly in the large firms.

Since the end of the 1970s, published output from South African occupational health research has increased somewhat. Much of this is collaborative research with independent trade unions. Research activity has advanced from clinical or pathological post-mortem case reports or series and cursory screenings to more sophisticated and carefully designed epidemiologic studies.

IV: Recent Events

The Commissions of Enquiry

Labor turbulence during the early 1970s led to a flurry of legislative activity and three state commissions of enquiry were established to investigate labor-related legislation: *The Erasmus Commission of Enquiry on Occupational Health* reported in 1975 on its investigations into the occurrence of occupational diseases, statutory protection of health at work, and occupational health services.[22] The findings were that:

- occupational diseases were widespread and highly prevalent in many industries;
- statutory protection of health at work was fragmented, incomplete, and out of date; and
- occupational health services outside of the mining industry were very limited.

Many specific recommendations were made with the major implications being that all workers should be covered by protective legislation and that a uniform industrial health policy and regulatory practice should be obtained. It was proposed that overlapping functions and costs should be eliminated by amalgamating all control within the Department of Health under the provision of one Act; that workers and their representatives be consulted about working conditions affecting their health; that employers be obliged to provide industrial health services, safe working environments and health information; and that an occupational disease database be established. The Commissioners stressed that in their view the situation was parlous and urgent and that speedy action was required. They emphasized that it was important to rectify poor working conditions before matters were taken up as organizational issues by Black labor.

The Wiehahn Commission of Enquiry into Labor Legislation reported in 1979.[15] The Commission was requested to bring the system of labor relations and the dispute-handling machinery into line with changed circumstances, and was charged with producing methods for constructing sound labor relations in South Africa. Workplace health and safety was a major area of enquiry. The main recommendations were that

- there should be a participatory dispensation for all parties and races in the economy;
- consultation and cooperation should take place between employers, trade unions and employees before changes were made or new developments introduced in the workplace; and
- industrial relations should be deracialized.

It was advocated that participation in the compensation process should take place by means of a Workmen's Compensation Board consisting of employer and employee representatives, which would review the provisions of the Act and its administration. The Commission's opinion was also that mining industry legislation should be deracialized with respect to both prevention and compensation.

The Nieuwenhuizen Commission of Inquiry into Compensation for Occupational Diseases reported in 1981.[23] The objectives of this Commission were to investigate and make recommendations relating to the differences between the two Acts in respect of all aspects of ascertainment, diagnosis, determination of disability caused by occupational diseases and the financing of compensation; and to look into the question of rationalizing legislation and practices. The Commission recommended integration of the two systems under the format operative in the mining sector. It advocated the tightening-up of compensation criteria in anticipation of the deracialization of the proposed new legislation and increased numbers of Black claims.

New Acts

New Acts and Bills in the area of occupational health and safety were not introduced until 1983: the Basic Conditions of Employment Act, 3 of 1983, the Machinery and Occupational Safety Act, 6 of 1983, and the Occupational Medicine Bill.

The Machinery and Occupational Safety Act was inspired by the legislation of other countries, especially the British Health and Safety at Work Act (1974) and attempted to modernize legislation relating to the protection of health and safety. As a piece of enabling legislation, it held out the possibility of moving toward increasingly stricter regulation of safety at work and the adoption of various standards relating to the use of hazardous substances (see below).

In many respects, the two new Acts only went part of the way toward meeting the recommendations of the Commissions. While legislation was modernized and deracialized, the objective of having a single Act was not achieved. Sexual discrimination was removed from the legislation by the Basic Conditions of Employment Act, but so was the protection (special health provisions) of women workers. None of the new laws included the trade unions as participants in the reforms and in the new structures that were introduced. The organizational structures laid down in the Machinery and Occupational Safety Act for factory health and safety were not consistent with the spirit of the Commissions as far as consultation with employees and trade unions was concerned.[24]

The new legislation signals the emergence of a changing perspective embodying contradictory trends. In some respects worker health and safety rights have been weakened, while in other respects new rights have been conferred and added responsibilities placed on employers.[25,26] Concern with regulating conditions must also be seen in conjunction with recent moves toward deregulation which is dealt with below. The removal of race and gender criteria from the body of labor legislation (including health and safety) has not constituted a significant reform since the composition of the labor force has in any case changed over the years resulting in a workforce that is today mainly Black with substantial female participation.

The Occupational Medicine Bill of 1983 proposed the establishment of factory-based health services along the line of the Erasmus Commission proposals. Unfortunately the Bill was inadequately drafted; it would have duplicated the factory inspectorate set up under the Machinery and Occupational Safety Act, and was ultimately dropped.[27]

During 1986, a Bill was put forward proposing amendments that would remove job reservation from the notorious Mines and Works Act, one of the most explicitly racially discriminating pieces of labor legislation on the statute books. Changes to the racial allocation of jobs could have an important effect upon labor participation in health and safety structures and practices on the mines. The National Union of Mineworkers, which has campaigned since its inception in 1983 for deracializing laws and practices on the mines, gave evidence to the Standing Parliamentary Select Committee on Mineral and Energy Affairs on their objections to the Bill. One of their main reasons for opposing the Bill was the wide discretionary power granted to the Minister, which would enable the retention of racial discrimination by ministerial proclamation despite the formal removal of racial criteria for holding skilled mining jobs.

Officials at the office of the Compensation Commissioner for Occupational Diseases in terms of the Occupational Diseases in Mines and Works Act have intimated* that attempts are currently under way to remove the racial basis for compensation awards under this Act, and to make

*Personal communication from the Office of the Commissioner.

earnings the basis of compensation. New measures flowing from the Nieuwenhuizen Commission are anticipated in the near future.[28]

While there have been some insignificant amendments to the Workmen's Compensation Act since 1981,[29,30] important compensation practices have been administratively altered behind the scenes, disadvantaging claimants (see below).

New Regulations

To date, a small number of regulations under the Machinery and Occupational Safety Act have been drafted. Some of these regulations are new, others are updated versions of pre-existing regulations. Only the General Safety, General Administration of the Act, and the Asbestos Regulations have so far become law. Regulations governing environmental conditions (noise, heat, and cold), general machinery, driven machinery, workplace facilities, and electrical machinery have been pending for long periods now. The regulations have generally taken a long time to pass from draft to final form and there has been concerted management resistance to new control measures, resulting in a weakening of successive drafts.[31] In some cases, notably the Facilities Regulations, the draft indicates a potential substantial weakening of benefits to workers when compared with regulations dating back to the 1960s or the 1940s. However, in the case of the general safety regulations, industrial workers are given some important new rights, and additional obligations are placed on employers. Thirteen years on the proposals for regulations in the Erasmus Commission report have by no means been adequately met.[32]

Deregulation

The Temporary Removal of Restrictions on Economic Activity Act was enacted in 1986, and represents a disturbing development with potentially severe implications for health and safety, as well as for wages and other conditions of work. In terms of this Act, laws may be suspended by the State President in any geographic area or industrial sector. In the field of health and safety for example, specified employers could be exempted from all legal responsibilities. Some limited protection of health and safety regulations is afforded by the stricture that the President must act on the advice of a standing committee of Parliament and in consultation with the Minister of Manpower. However, protection would only be exercised effectively by union lobbying at this level.

The underlying purpose of this Act appears to be the promotion of free enterprise and small business, in particular by removing "restrictive legislation" by presidential decree. It is very likely that this Act will be applied to the most vulnerable, unorganized workers, whose conditions are generally the worst.

The implementation of deregulation via legislative initiatives has been accompanied by a great interest in privatization, which appears to be the dominant trend in state and management economic thinking. The contradictory picture that has emerged of worsening conditions and practices, alongside new regulations and deregulation seems to reflect conflicting thinking in the state with regard to an economic goal of privatization, and the objective of an acceptable industrial relations environment.

Social Forces in Conflict: Two Examples

Both management and the state have been alarmed at working class activities since the early 1970s. Labor-linked health and safety activities have increased steadily and there have been a series of management and state responses calculated to preempt worker organization, disrupt production, and erode managerial prerogative at the workplace. These conflicts will be illustrated by means of two examples: the safety representatives and safety committees of the Machinery and Occupational Safety Act, and struggles over worker compensation for occupational lung disease.

Example 1: The Act, Safety Representatives and Safety Committees

The response of state and management to the Act is an instructive lesson in the sociology of shop-floor primary health care. The law is imprecisely worded and thus permits different views regarding its implementation. According to the Act safety representatives are to be designated in writing by management and this has been interpreted by management to mean that they are management appointees; it is also assumed that safety representatives should be literate (most Black workers are not) and should have completed training courses certified by the National Occupational Safety Association before being eligible. There also has been a strategy of appointing only supervisors and managerial personnel, who are usually White, as safety representatives.[24] This has resulted in production workers and their elected representatives being bypassed.

Organized labor on the other hand has endeavored to democratize the application of this law by negotiating the right to elect safety representatives, by reserving the right to negotiate health and safety issues through representative shop stewards' committees, by avoiding the management-dominated joint safety committees, and by extending rights in health and safety agreements far beyond the provisions of the Act.

Example 2: Compensation for Occupational Lung Diseases

Since the end of 1984, changes in Workmen's Compensation practices have taken place which place workers at a disadvantage. In the last few years large numbers of compensable occupational disease cases, particularly pneumoconiosis, have been generated in the wake of union-related health screening programs.[33–36] The reaction of the compensation authorities has been to make benefits for occupational disease less accessible and less favorable to workers. In 1984 the Workmen's Compensation Commissioner prevented the joint Bureau-Center certifying panel from certifying cases as compensable disease for submission, unless cases were seen personally at the Center's clinic in Johannesburg.[37] This meant that it was no longer possible to have the medical particulars of suspected cases outside of the Johannesburg area forwarded for certification to the joint panel prior to submission to the Commissioner for compensation.

In late 1985, the disability classification for workers with occupational chest diseases was revised administratively by the Commissioner. Before that time, workers with radiographic evidence of pneumoconiosis as their only manifestation of an occupational disease were assessed as 35 per cent disabled; this was the lowest category of disablement for occupational lung diseases and entitled workers in this category to a lifelong pension. After the revision, the lowest disability category was set at 20 per cent and entitled workers in this category to a lump sum payment only. In money terms, the value of the benefit was thereby reduced to between a third and a half of its former value depending on the age of the worker.[38–40] This disadvantageous revision was introduced with no reference to organized labor and attempts to raise the matter directly with the Commissioner or indirectly via Parliament proved unsuccessful.

The revision was immediately applied by the state medical certification bodies. Observations from industries like the asbestos-cement industry are that virtually all cases of asbestosis now certified are receiving the lump sum payment instead of the pension. A further disadvantage is that the company pensions which had previously supplemented the Commissioner's pension to 100 per cent of the last basic wage, and allowed workers with asbestosis to opt for voluntary retirement on these terms, are being withheld from those now classified as only 20 per cent disabled. Total compensation in these cases consists of the lump sum from the Commissioner.

Conclusion and Future Implications

The past 15 years have been characterized by a process of tentative governmental political and labor reforms in South Africa. However, political exclusion of Blacks, privileged relations between management and state, and the underlying hostility of the state towards labor which has frequently erupted despite legislative reform, have created a negative climate for co-optation of Black labor militancy. The state has failed to fob off workers' political demands with substitute trade union rights.[41]

In the field of occupational safety and health there has been a process of reform characterized by a technical updating of legislation appropriate to new developments in industrial production. The social content of this reform is conservative: labor has been excluded from a participatory role at the various levels of regulation. Workers and their organizations remain suspicious of reform initiatives that do not specifically include them in a representative way.

A number of new legislative measures evince contradictory state thinking. On the one hand there are new regulations which rely on management self-regulation and are in some cases weaker than pre-existing legislation, and on the other hand there are deregulatory measures. Changes to compensation practices have been put into effect, affecting workers with chronic lung disease in dust-producing industries; similar changes are embodied in draft legislation currently being considered by parliament. Early indications[24] that the Machinery and Occupational Safety Act enshrined the principle of management self-regulation and the exclusion of labor have been borne out by the method of its implementation and the method proposed for monitoring new draft regulations. There is little evidence of any increase in the activity or efficacy of the factory inspectorate. For the foreseeable future, the state appears to be headed for a minimalist role in occupational health, with increased legislative activity but only formal and weak control over the work environment.

The new legislation will most probably lead to an increase in the numbers of occupational health care professionals. Indications are that they will be inserted into a privatized network of services paid for and directly controlled by management.

The role of labor has been mainly confined to taking up issues at a shop floor level. At the national level, some progress has been made in negotiating health and safety conditions in the asbestos industry, while the National Union of Mineworkers has made important submissions to the parliamentary standing committee charged with redrafting the Mines and Works Amendment Bill. Neither the COSATU nor NACTU have thus far developed a health and safety policy or program, although one is currently being considered by COSATU. The past three years have been associated with weakened labor health and safety activity as a result of the depletion of union administrative resources by state action against union members and officials, including two States of Emergency, as well as the effects of the economic recession. The absence of worker participation in the legislative process could lead to a situation where legislation and practices now being established may be seen as technical and socially neutral, not requiring transformation in a possible post-apartheid South Africa, and survive into the future relatively intact.

There appear to be compelling reasons for coordinated labor responses to halt the creeping disaster of deregulation, and to influence the modernizing of health and safety regulation which is now taking place. However, one of the effects of the States of Emergency has been to harden anti-state feeling on the part of workers and their organizations, and this could reinforce the tendency to avoid dealings with the state as a matter of principle. The important question is whether unions will follow the example of the mineworkers and engage the state through the national labor federations with the aim of influencing the legislative process. This may be appropriate, particularly in areas such as changes to the compensation procedure, or attempts at deregulating certain sectors of the economy, where more direct and participatory forms of worker action are very difficult. In these instances, direct labor input on key measures at the national federation level may be the only way to decrease labor's vulnerability to the designs of management and the state.

Management has been able in many instances to use the recession and the disinvestment and sanctions campaigns to place unions on the defensive in wage and other bargaining by portraying labor and other popular organizations as the root causes of disinvestment and sanctions. One example in the health and safety area is that of halting the practice of substituting dangerous substances like asbestos in construction materials on the grounds that imported materials are more costly. Poor exchange rates, which are inextricably bound up with the political situation, were blamed. In another case, the management of a chemical factory where a number of workers had been poisoned claimed that they could not afford effective protective measures as their foreign parent company had decided to disinvest.

In most workplaces management has made changes during the past two years to comply with the legal requirements to implement health and safety structures laid down by the Act. However, working conditions in many factories still contravene legal requirements, and the topdown approach to the implementation of safety structures produces a strong impression that the Act has been extensively implemented in form rather than in depth.* Delays in the passing of draft regulations suggest management opposition to major changes aimed at improving health and safety, and concerted efforts to promote their interests in the regulation process. This would be consistent with the overall developing economic program, shared by the government and capital, comprising conservative measures such as privatization, deregulation and other anti-labor economic policies, which simultaneously represent a threat to safe and healthy working conditions. These responses reveal the way in which health and safety is continually weighed up against other cost factors to the

*Macun I: The Implementation of the Machinery and Occupational Safety Act. Paper No 8 XVIIIth Annual Congress of the Association for Sociology in Southern Africa, Cape Town, 1987.

enterprise, rather than being viewed as an important worker right.

Occupational health is a significant aspect of the well-being of a population. This paper has attempted to show the importance of the participation of worker-patients in the amelioration of occupational health problems historically and currently, and the linkage between labor organization and improvements in the work environment. The conservative nature of occupational health system reform in South Africa and the current trajectory of labor suppression threaten to exclude labor as a participant in this system. This raises the question as to whether labor's occupational health gains will be maintained or lost in the future.

AAPHD Issues Call for Abstracts for 1989 Meeting in Honolulu

The American Association of Public Health Dentistry (AAPHD) has issued a call for abstracts for its 52nd annual meeting, to be held November 1–3, 1989 in Honolulu, Hawaii. Papers on a broad range of dental public health subjects are invited, and a special call was sounded for international reports, due to the setting and the theme.

The theme of this years AAPHD meeting is "Commitment and Caring: The Challenge for the Next Century." Key topics suggested by the program planners include: trends in oral disease; innovative preventive and educational measures; national and local dental programs; dental care delivery systems; ethics and access to care; oral health for special population groups; effects of technology on dental public health; AIDS; infection control; and other related topics. *Abstracts are due by April 1, 1989.*

For further information, and rules for submitting an abstract, contact the AAPHD Program Chair, E. Joseph Alderman, DDS, MPH, Director of the Office of Dental Health, 878 Peachtree Street, NE, Room 215, Atlanta, GA 30309.

The American Journal of Public Health, published monthly, is the official Journal of the American Public Health Association, Inc., 1015 15th St., NW, Washington, DC 20005. Founded in 1872, the American Public Health Association is organized to protect and promote personal and environmental health by exercising leadership in the development and dissemination of health policy. Representing all disciplines and specialties in public health, APHA is the largest public health association in the world, with an aggregate membership of 50,000, including its state and local affiliates.

Manuscripts, Correspondence, and Letters to the Editor: Send to Alfred Yankauer, MD, MPH, Editor, *American Journal of Public Health,* 1015 15th St., NW Washington, DC 20005.

Information on Manuscript Preparation is published in this Journal in January, April, July and October. The Journal publishes reports of original research, demonstrations, evaluations, and other articles covering current aspects of public health. Manuscripts are accepted for consideration with the understanding that they, or their essential substance, have not been published previously or accepted for publication, and are not under consideration elsewhere.

Subscription Price is $80/year domestic, $120/year foreign, single copies are $8 domestic and $12 foreign. Prepayments only.

Postal Information: Second class postage paid at Washington, DC and additional mailing offices. Postmaster: Send address changes to American Journal of Public Health, 1015 15th St., NW, Washington, DC 20005. AJPH allotted $40; TNH allotted $6 of APHA membership dues. Information on individual membership appears elsewhere in this Journal, or contact: Director, Membership Services, at APHA headquarters in Washington, DC.

both federal and local levels between public health workers and others with legitimate concerns in this field.

This issue of the Journal features a wide range of papers addressing both intentional and unintentional injuries as well as basic research and evaluation of intervention efforts. Such a gathering of papers is possible because more public health workers have been entering the field, in many cases through new or revitalized formal programs in health departments and schools of public health. Their efforts are beginning to bear fruit. It is noteworthy that this issue also contains a research contribution from France, reflecting in part recent efforts by the World Health Organization to promote injury control research and public health programs throughout the world.

It is axiomatic in the field of movie-making that the sequels are never as good as the original. In the field of public health, however, we have substantial hopes—and some promise—that "Injury Control IV" will be the best yet.

Survival Experience of Aged Hip Fracture Patients

JAY MAGAZINER, PHD, MSHYG, ELEANOR M. SIMONSICK, PHD, T. MICHAEL KASHNER, PHD, J. RICHARD HEBEL, PHD, AND JOHN E. KENZORA, MD

Abstract: Hip fracture has long been considered a major threat to survival in aged populations. This report describes the survival experience of 814 aged, community dwelling hip fracture patients treated in seven Baltimore hospitals between 1984 and 1986: 4.3 per cent died during hospitalization; 8.2, 12.6, and 17.4 per cent died within three, six, and 12 months after fracture, respectively. The mortality rate for the entire population approaches expected mortality approximately six months post-fracture, but varies by age and sex. The most important factors predicting mortality are presence of serious concomitant illness and marked delirium (in the absence of dementia) at the time of hospital admission. The authors suggest that medical factors that may contribute to patient disorientation be investigated and treated, when possible, in an effort to improve the survival status of hip fracture patients. (*Am J Public Health* 1989; 79:274–278.)

Introduction

This report describes the survival experience of a recent series of hip fracture patients who entered one of seven Baltimore area hospitals between October 1, 1984 and April 30, 1986. While the survival experience of numerous series of hip fracture patients has been previously reported, the majority of these include patients treated in the late 1950s to mid-1970s,[1–25] generally before the initiation of prophylactic anticoagulant and antibiotic treatment for surgical patients.[13] Secondly, most recent hip fracture series involve patients treated outside the United States,[26–34] where treatment principles and use of technology differ markedly from those in this country.[35] Moreover, most previous reports do not differentiate the mortality experience of individuals residing in nursing homes or other long-term care institutions at the time of fracture from that of community dwelling patients,[1,3,5–11,13,15–17,19,20,22,24,25,31] and numerous studies[1,2,5,6,8,9,11,13,17,19–23,31,32,36,37] include hip fracture cases younger than age 55 for whom the cause of fracture is often severe trauma and for whom the prognosis of recovery is generally excellent.[3,24,25,37]

The present study provides more current information on the survival experience of aged hip fracture patients treated in the United States, and residing in the community at the time of their fracture, and determines at three, six, and 12 months following hip fracture the relative risk of mortality associated with selected demographic and medical indicators.

Methods

Subjects and Data Collection

Subjects consist of all patients aged 65 years or older, admitted to one of seven Baltimore area hospitals from the community with an acute fracture of the hip between October 1, 1984 and April 30, 1986. We identified the majority of patients (n = 698) through weekly calls to an established contact within each hospital, usually an orthopedic ward nurse or an admissions officer. To ensure complete enumeration of eligible cases, we reviewed hospital discharge records for cases discharged with an ICD-9 code of 820 not previously identified. An additional 116 cases were located in this manner. Data on all patients (n = 814) were obtained from hospital charts by trained interviewers using a standard protocol.

The seven study hospitals were selected on the basis of the volume of patients treated using data from the Maryland Health Services Cost Review Commission. These hospitals treat approximately half of all hip fracture patients age 65 and older treated within the 27 hospitals in the Baltimore SMSA. Study hospitals comprise a broad range of practice settings, including urban, suburban, sectarian, and public hospitals. Three of the seven hospitals have orthopedic residency programs. Elderly hip fracture patients treated in the study hospitals compared with those seen in all Baltimore area hospitals are more likely to be older than 75 years (79 per cent versus 75 per cent), female (83 per cent versus 79 per cent) and discharged to nursing homes (39 per cent versus 34 per cent).

Measures

Predictors—The demographic factors examined in this study include: age, sex, and race. The medical predictors include: type of fracture (intracapsular or extracapsular), orientation on admission, and concomitant medical conditions. The measure of orientation on admission derives from physician chart notes regarding patient status on admission. If disorientation was noted, the patient was labeled confused; if unnoted, the patient was considered mentally clear.

To account for patients' medical status pre-fracture, we constructed a binary measure of general medical condition based on whether any of the following conditions were noted in the patient's chart: cancer; stroke and related conditions; heart, atherosclerotic, liver, bladder, pulmonary, or renal disease; chronic obstructive pulmonary disease (COPD); or Parkinson's disease. These conditions were selected on the basis of previous findings involving single disease entities and mortality following hip fracture[1,9,16] and on clinician judgment. We constructed a binary measure of cognitive status based on whether or not senile dementia, Alzheimer's disease, or organic brain syndrome were noted in the hospital chart. Using this measure and an additional item concerning orientation on admission, we developed a three-category variable. The reference category includes patients with neither dementia nor noted delirium on admission; the second, consists of only patients with dementia; the third, includes cases with noted disorientation on admission, but who were not diagnosed as suffering from an organic brain syndrome. We chose to distinguish between chronic confusion due to dementia and acute confusional states or delirium

as the latter often indicates the presence of a potentially serious biomedical condition or metabolic disturbance which can deleteriously affect patient outcome.[17,38]

Outcome—We obtained the survival status of patients and date of death (when applicable) through follow-up interviews of the patient or a close friend or relative of the patient at two, six, and 12 months following hospital discharge. For 119 patients for whom we could not obtain follow-up interviews and the 116 patients identified through discharge diagnoses, the investigators searched the death records maintained by the Maryland Bureau of Vital Statistics for each patient's name and date of birth. When a match was found, staff recorded the date of death. If no death record was found, the patient was presumed still living.

Using the date of death for patients who died and the date of hospital admission, we calculated the number of days each patient survived since sustaining a hip fracture. Since hospitalization generally occurs within one or two days following a hip fracture,[22] we used the date of hospital admission as a reasonable approximation of the date of fracture.

Data Analysis

We calculated the expected one-year mortality using 10-year age group-, sex-, and race-specific death rates published by the National Center for Health Statistics for the United States population in 1982.[39] We calculated the observed mortality rate for each month following fracture and compared this with the expected death rates. In plotting the expected survival curve and in calculating the expected monthly mortality, we assumed that change in mortality is directly proportional to time over the one year follow-up period.

To examine the relative predictive value of the demographic and medical factors, we first tested for the presence of an association between each variable of interest and mortality at three, six, and 12 months post-fracture, using Yates' chi square statistic for dichotomous measures and Mantel-Haenszel's test statistic for variables with three or more ordered categories. We performed logistic regression analyses with mortality as the outcome for each time period after fracture. Odds-ratios and 0.95 confidence intervals were calculated for each factor using the beta coefficients and standard errors generated by the regression procedure following the method prescribed by Schlesselman.[40]

Results

Table 1 describes the demographic and medical characteristics of 814 patients followed for one year after sustaining hip fracture. The population consisted largely of White females with an average age of 80 years. Patients were relatively unhealthy with over 70 per cent having one or more serious concomitant illnesses and 8.6 per cent suffering from organic brain dysfunction. Thirty-seven patients (4.3 per cent) died before hospital discharge—all but one within 40 days of admission.

The proportion of patients dying within three, six, and 12 months following hip fracture is 8.2, 12.6, and 17.4 per cent, respectively. Figure 1 plots the observed and expected one year survival curves for the total population and for the population subgroups. Hip fracture patients clearly experience greater mortality than persons of similar age, race, and sex. The degree of excess mortality, however, varies by sex and age. At one year the difference between the observed and expected mortality rates is greater for males than females and greater in patients younger than 75 years than older patients. The point at which the observed survival curve parallels the expected survival curve also varies by age and by sex. The death rates for female patients and patients 85 years or older approach expected rates approximately six months post-fracture. Patients between 75 and 84 years of age experience similar mortality as expected at about 10 months after sustaining hip fracture. Elevated mortality for both males and the youngest patients appears to continue beyond the first year post-fracture.

TABLE 1—Demographic and Medical Characteristics of 814 Hip Fracture Patients, Ages 65 and Older Admitted to Seven Baltimore Area Hospitals, October 1984 to April 1986

Characteristics	Per Cent (Years)
Gender	
Male	20.2
Female	79.8
Race	
White	93.5
non-White	6.5
Age	
Mean	(80.1)
65–74	24.2
75–84	45.3
85 or above	30.6
Type of Fracture	
intracapsular	45.2
extracapsular	54.8
Concomitant severe physical illness	70.6
Dementia noted in medical chart	11.8
Delirium on admission	19.3
Delirium on admission, exclusive of dementia	7.5

Table 2 presents the relative risk of mortality at three, six, and 12 months following hip fracture associated with the seven demographic and medical factors examined. The presence of at least one life-threatening condition as noted in the patient's medical chart confers the greatest risk of mortality relative to the other factors examined at three and six months following fracture. This elevated risk diminishes with increasing time since fracture from 4.6 to 2.6 times the risk experienced by patients wtih no concomitant illness. Patients with dementia do not experience an increased risk of mortality following fracture; confidence intervals of any apparent protective effect of dementia are very wide, however. Patients with noted delirium on admission who had no history of dementia have 3.1 to 3.5 times the risk of dying as cases who were not disoriented when admitted to the hospital or who had a history of cognitive impairment.

Patients older than 84 years of age have 2.6 times the risk of dying within three months of hip fracture as patients between ages 65 and 74 years, decreasing by six months after fracture. Patients between ages 75 and 84 years do not experience an increased risk of mortality relative to patients between ages 65 and 74 years. These findings, with respect to age, are particularly noteworthy given that the expected death rate for persons 85 years of age and older is nearly six times the mortality rate for persons between ages 65 and 74 years (14.6 per cent versus 2.5 per cent) and the expected death rate in persons 75 to 84 years old is more than twice that of the rate for persons between ages 65 and 74 years (5.8 per cent versus 2.5 per cent). As expected the relative risk of mortality associated with male sex increases from 1.4 to 1.9 over time.[39] The small proportion of non-White cases (6.5 per cent) makes any finding, regarding race, difficult to interpret.

The relative risk associated with each factor after adjusting for the other factors in the models does not differ greatly from the unadjusted relative risk, except for a slight reduction in magnitude evident for each factor across all time periods.*

*Data available on request to authors.

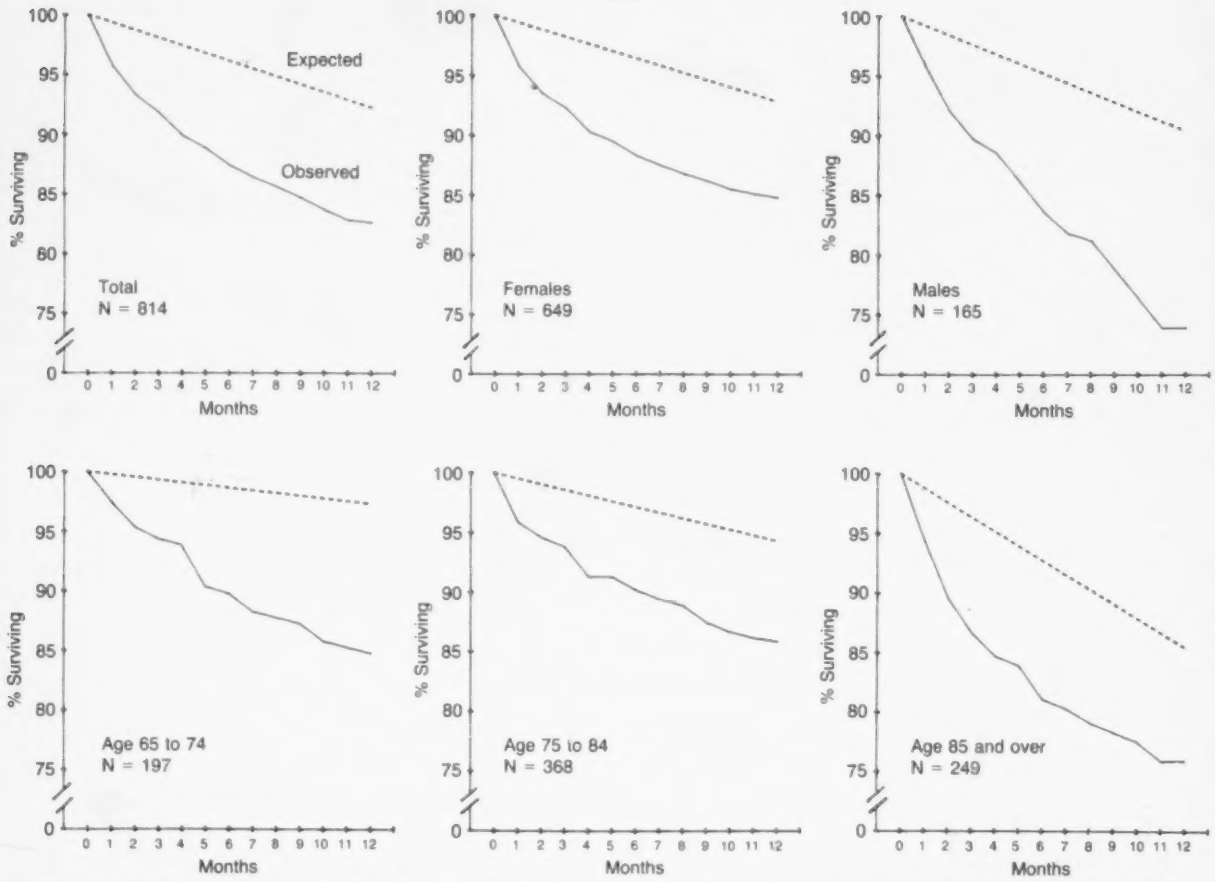

FIGURE 1—Observed and Expected Survival Curves by Sex and by Age Group for 814 Hip Fracture Patients, Ages 65 and Older, Baltimore 1984 to 1986.

Figure 2 presents the probability of one year survival given patient sex, age category, illness state, and orientation at the time of hospital admission independent of dementia. Delirium is present in a relatively small proportion of patients—7.5 per cent overall and no greater than 16.2 per cent in any subgroup. Patients older than 84 years and patients with at least one serious medical condition are more likely to become notably disoriented following their fracture than younger and healthier patients. In comparing subgroups similar in all respects except orientation on admission, we find that in all instances where valid comparisons can be made, patients with delirium on admission experience a lower probability of survival than patients with either normal orientation or a history of dementia. For female patients with no serious concomitant disease, the observed survival rate does not differ from the expected rate in either young or old patients. This relation does not hold for male hip fracture cases. Lastly, patients with serious medical problems have a lower probability of survival than patients without any serious medical conditions whether or not they become disoriented.

Discussion

Studies of mortality following hip fracture are characterized by diversity in patient populations, length of follow-up, and country of treatment. This diversity renders assessment of recent secular trends in post-fracture survival difficult, although it appears that mortality rates among hip fracture patients have generally declined between the late 1950s and the mid-1970s.[13] As such, the comparison of findings with previous work is limited to case series treated in the 1970s and later.

The in-hospital mortality rate of the current series of fracture patients is 4.3 per cent, considerably lower than the 18 and 21 per

TABLE 2—Unadjusted Relative Risk of Mortality at Three Points in Time Following Hip Fracture Associated with Selected Factors in 814 Patients Ages 65 and Older, Admitted to Seven Baltimore Area Hospitals, October 1984 to April 1986

Factors	Months Since Hip Fracture		
	Three	Six	Twelve
Sex (male)	1.4 (0.8,2.4)*	1.5 (0.9,2.4)	1.9 (1.3,2.9)
Race (non-White)	1.5 (0.6,3.6)	1.9 (0.9,3.8)	1.8 (0.9,3.3)

cent mortality found for two similarly aged patient series treated, respectively, in Great Britain[26] and in Ireland[27] in 1981. The length of hospital stay for those patients averaged over 30 days, however, compared with less than 20 days for the current series. Our in-hospital mortality rate (4.3 per cent), compares favorably to the 2.0[32] and 5.8[36] found in two other recent series treated in Scandinavia that included patients as young as 50 years of age. Differences in in-hospital mortality across studies may reflect gross differences in treatment procedures, health status of patients, and/or age distribution of patients treated. While none of the case series described above include institutionalized patients, criteria for placement in and the definition of long-term care facility may vary greatly across cultures.

The one year mortality of patients in the current series (17.4 per cent) is similar to that found in two series, treated in Denmark between 1977 and 1978, that exclude non-elderly patients. One[36] had a six-month mortality of 11.1 per cent; the other,[28] 20 per cent. Differences in observed mortality reported in other studies[29,32,37] appear strongly related to the age distribution of the respective patient populations reviewed.

The observed and expected survival curves for the current series become approximately parallel six months post-fracture, but this point varies by age and sex. This finding generally agrees with earlier studies which report that a substantial portion of excess mortality occurs in the first few months following fracture.[35] Estimates from other studies of patients hospitalized since the late 1960s[5,24,28] of the point at which the mortality curve begins to parallel that for a cohort matched by age and sex range from three to 12 months.

Several investigators[1,15,19] have found a secondary rise in mortality at varying points following hip fracture ranging from four to six weeks to four to five months. Inspection of the survival curves and monthly mortality rates by age group in the current series suggests a similar phenomenon. This may reflect random variation in mortality rate rather than a true change in slope, but the possibility that a true secondary rise in mortality exists warrants exploration.

We found male sex, advanced age, presence of at least one serious illness, and delirium at the time of admission (exclusive of dementia) to represent threats to survival in the first year following hip fracture. Several previous studies report similar findings, with regard to sex, age, and concomitant disease.[1,3–5,13,24,28,33] Contrary to our finding that dementia is not associated with a higher rate of mortality, other investigations[1,24] find the presence of organic brain syndrome highly predictive of death within one year of hip fracture. These earlier reports, however, include patients from extended care facilities who may have had more advanced cases of dementia than the present community dwelling population; this difference could account for their higher death rates. While no previous reports examine the relationship between delirium at the time of hospital admission independent of dementia, the results from two prior studies are suggestive. Matheny and associates[17] found that patients who became disoriented during their hospitalization experienced much higher in-hospital mortality than patients who remained mentally clear throughout their stay (20.7 per cent versus 1.1 per cent). Barnes, *et al*,[4] examined blood urea (whose elevated levels are associated with acute confusion)[41] found the death rate among patients with elevated levels (>80 mg per 100 ml) died at five times the rate of patients with low levels (<40 mg per 100 ml).

How hip fracture contributes to delirium and why this

acute confusional state increases risk of mortality are important questions. While this area remains largely unresearched with respect to hip fracture cases, two reports offer some insight. Matheny, *et al*,[17] contend that post-fracture and post-surgical delirium may signify blood sugar or electrolyte aberrations, renal failure, infection, drug intoxication, among other clinically relevant states. Kenzora and associates[13] further suggest that patients who experience a delay in receiving medical attention may become dehydrated and that surgery before restoration of blood, fluid, and electrolyte balance may overwhelm the patient's capacity to make adequate physiologic adjustments. Taken together, these observations imply that mortality associated with patient disorientation may be amenable to treatment. Our findings tend to support this premise as marked disorientation on admission was found to make an independent contribution to patient mortality.

Several caveats are in order:

- The first concerns the dependence on medical chart notes for the measurement of dementia, confusion, and other significant medical conditions. The possible problems include: underreporting of serious medical problems, inability to evaluate the severity of various disease states, and mistaking delirium at the time of admission for dementia and visa versa.
- Second, the study population may not represent the universe of aged hip fracture patients residing in the community, as study hospitals were selected on the basis of the volume of patients treated and not for their case mix.
- Similarly, the exclusion of nursing home patients necessarily excludes patients in the poorest health. Thus, conclusions based on the current study population may not apply to all hip fracture cases.
- Fourth, the inability to determine the contribution of various disease conditions to mortality in the general population renders it impossible to distinguish the true contribution of hip fracture to patient mortality over that expected for a person with a similar health profile.
- Lastly, patient delirium noted on admission may have preceded the fracture—not followed from it.

Despite these limitations, our data indicate that excess mortality associated with hip fracture depends primarily on pre-fracture disease state and secondly on entering the hospital in an acute confusional state. Clearly, patients' pre-fracture medical status cannot be modified; however, fracture-related delirium is potentially treatable. This finding argues for careful investigation of factors that contribute to delirium as part of the standard treatment strategy.

Determinants of Recovery 12 Months after Hip Fracture: The Importance of Psychosocial Factors

JANA M. MOSSEY, RN, MPH, PHD, ELIZABETH MUTRAN, PHD, KATHRYN KNOTT, RN, AND REBECCA CRAIK, PHD, LPT

Abstract: The independent contributions to recovery from hip fracture of psychosocial factors including depression, personality, social connectedness, and self-rated health were studied in 219 women age 59 and older (mean age 78.5) who were community dwelling prior to fracture. Initial assessments were conducted shortly after surgery and follow up assessments 2, 6, and 12 months later. By 12 months, 15 patients had died and 15 had entered a nursing home. Substantial declines in physical functioning though not psychosocial status were observed. Only 21 per cent (compared to 81 per cent prefracture) reported walking independently; fewer than 30 per cent had regained reported prefracture levels of physical function. The proportion with elevated depression scores at 12 months was 20 per cent, down from 51 per cent following surgery; 64 per cent rated their health excellent or good at 12 months, up from 43 per cent after surgery.

Poor cognitive status and post-surgical self-rated health were predictive of mortality. Among survivors, age, prefracture physical functioning, and cognitive status were associated with recovery in physical function but not psychosocial status. High post-surgery depression scores, but not the other psychosocial factors, were associated with poorer recovery in both functional and psychosocial status. These findings demonstrate the importance of depressive symptoms as one determinant of recovery from hip fracture and support the need to attend to the affective status of hip fracture patients following surgery. (*Am J Public Health* 1989; 79:279–286.)

Introduction

Fracture of the hip represents a public health problem of increasing magnitude. Annual incidence in the United States is estimated to be approximately 98 fractures per 100,000 population.[1–3] The majority of hip fractures (70–80 per cent) occur in females over 60 years of age, with the population at highest risk being White females 85 years or older.[4] While there are sophisticated surgical procedures for hip fracture repair, full recovery has been elusive. Only 12 to 23 per cent return to prefracture ambulatory status and/or functional independence.[5,6] Mortality rates in the first 12 months following fracture are 12 to 20 per cent higher than in comparable age/sex groups in the general population,[3,7–9] and rates of institutional placement during the immediate post-hospital period are high and remain higher than average as the individual grows older.[10,11]

Case series data[6,9–11] consistently have shown prefracture physical and cognitive function and age to account for a substantial amount of the variance in hip fracture recovery. While there is evidence suggesting that psychological, social, and environmental factors influence recovery as well,[6,12] evaluation of the contribution of a broad range of factors has been rare. Information regarding both physical functioning and psychosocial status, measured either before or after fracture, usually has not been available. Moreover, most studies have included both seriously debilitated, older individuals with limited potential for any recovery, and "healthier" elderly with a more positive prognosis. Consequently, even when psychosocial variables have been studied, there has been limited ability to evaluate the independent importance of these factors for recovery over and above the effects of the individual's health status.

We undertook a study designed to specifically investigate the role of psychosocial factors measured after surgery in the recovery of the "healthier" hip fracture patient. In this paper, we characterize their recovery status 12 months following surgery. We also present the findings of analyses to evaluate the independent contribution to recovery of four psychosocial factors measured during the initial, post-surgery assessments: self-rated health, depressive symptomatology, personality, and social supports. There is considerable evidence supporting the prognostic significance of these factors for the clinical course and/or recovery associated with diverse illnesses. The reader is referred to the excellent review by Kasl[13] for a critical appraisal of this literature.

Methods

Study Sample

Subjects were recruited from among community dwelling, ambulatory White females over 59 years of age who were treated surgically for a fractured hip in one of 17 hospitals in the greater Philadelphia area between August 1, 1984 and January 15, 1986. Initial structured interviews were completed as soon after surgery as possible (usually the 7th-20th day). Follow-up interviews were obtained two and six months later and a final telephone interview was conducted 12 months after surgery. Clinical assessments of walking ability and neuromuscular status two and six months postsurgery were also made, and the patient's hospital record was systematically reviewed.

Seven hundred and thirty individuals meeting the above age, sex, race, and residence criteria were identified at the time of surgery; they represent an almost complete ascertainment of the patients treated during the surveillance period in each hospital. Additional study criteria included: ability prior to fracture to walk across a room with no greater assistance than a straight cane, absence of post-surgical cognitive impairment that would preclude completion of study assessments and absence of cancer or other health problems likely to cause a pathological fracture or to result in death during the year following hip fracture. Three hundred and sixty-two patients met these criteria and were asked to participate in the study; 219 of these consented.

The sample for this analysis, consists of the 211 individuals (96 per cent of those enrolled in the study) for whom complete post-surgical and follow-up data or documentation of death were available. Mean age of these individuals was 78.5 (s.d. 7.6). Prior to hip fracture, 55 per cent lived alone, 21 per cent lived with their spouse, and 24 per cent with friends or other relatives. Forty-eight per cent were of British or Irish ethnic origin; 25 per cent reported German descent, and 15 per cent and 11 per cent, respectively, were from Eastern Europe or were listed as other. Mean level of education was 11.6 years (s.d. = 3.4). Forty-three per cent of the study subjects sustained a fracture of the trochanteric or intertrochanteric region of the femur. An intercapsular fracture was reported for 36 per cent and a fracture of the subtrochanteric or femoral neck region was recorded for the remaining 21 per cent. For 65 per cent of subjects, hip fracture repair involved fracture reduction and fixation; for 35 per cent a partial or complete prosthesis was used.

Some information obtained during study enrollment was available for both the 211 patients in this analysis and those who refused the initial interview (n = 143) or who were excluded because of missing data (n = 8). In addition, survival status at 12 months was known for 94 per cent of the 143 refusers and 103 (72 per cent) completed the 12-month interview. Comparisons of study participants and non-participants revealed no differences ($p < 0.05$) between the groups in terms of: age, prefracture living arrangement, prefracture independence in ambulation, history of recent fracture, prefracture pain or observed physical or sensory impairments. At 12 months, there were no differences between participants and non-participants in terms of survival or any other recovery indice.

Study Variables

In addition to information on sociodemographic variables such as age, marital status, and education, variables pertinent to this report include:

- *Prefracture Health Status:* The number of health problems experienced in the preceding year was assessed during the initial post-surgical interview using a modified version of the health problems scale in the Multi Level Assessment Instrument (MAI).[14] Two additional questions were included to assess the presence and constancy of pain prior to hip fracture. Information abstracted from the patient's hospital record included the number of hospitalizations in the two years preceding the hip fracture and the number and type of different diagnoses reported on the admission history. Data on the type of diagnoses were used to classify individuals according to the number of serious diagnoses reported.
- *Prefracture Functional Status:* Ability to perform self-care activities of daily living (ADL) such as bathing, and dressing, and instrumental activities of daily living (IADL) such as shopping and doing housework prior to hip fracture were assessed retrospectively during the initial post-surgical interview. An adaptation of the Multi-level Assessment Instrument was used.[14] ADL and IADL scores were computed as the number of activities that the individual reported doing without any assistance. Difficulty in performing activities such as pushing, pulling, and carrying objects was measured with three items adapted from disability scales developed by Nagi.[15] The presence and kind of assistance required in walking or traveling distances were also determined.

  Predictably, the above measures of prefracture functional status were correlated. To minimize potential problems resulting from multicollinearity and to simplify the analytic models, a principal components analysis that included the function scales was done. This yielded a single factor. Factor loadings were used to compute a summary prefracture physical function score. Scores ranged from −4.33 (poor function) to .92 (good function).
- *Cognitive Function:* The Short Portable Mental Status Questionnaire (SPMSQ)[16] was administered during the initial interview to assess post-fracture cognitive function in terms of orientation, memory and abstraction ability. Of the 10 SPMSQ items, eight were asked; the questions on year of birth and age were omitted.
- *Psychosocial Variables:* Two subjective measures of global health status based on responses to the question, "How do you rate your health: excellent, good, fair or poor?", were obtained during the initial post-surgical interview. For one, individuals were asked to rate their health as they remembered it to be "just prior" to their hip fracture; for the other, a rating was obtained for current health status "today". The presence of depressive symptomatology experienced the week preceding the post-surgery interview was assessed with the Center for Epidemiological Studies Depression Scale (CES-D).[17,18] Recent evaluation of this 20-item scale confirms its validity as a measure of depressive symptomatology with older individuals, even those who are physically ill or disabled.[19] Scores range from 0 to 60 with a score of 16 or higher distinguishing those with a high probability of clinical depression.

  Personality dimensions of neuroticism and extraversion were measured by the Eysenck Personality Inventory.[20] This instrument contains 52 "yes/no" questions of which 24 are markers for each personality trait. The Eysenck Inventory has been extensively used in personality research. Recent reviews confirm the validity of the neuroticism scale and, to a lesser extent, the extraversion scale in older populations.[21,22]

  Social support, defined in terms of the availability and usual frequency of contact with children, close relatives, close friends and a "special person" with whom intimacies are shared was assessed using questions adapted from the National Institute on Aging project "The Establishment of Populations for Epidemiologic Studies of the Elderly" (EPESE).[23]
- *Treatment-Related Variables:* Fracture site (e.g., trochanteric, subcapital, intertrochanteric), repair type (pin or prosthesis), pre- or post-surgical medical events (e.g., fever, wound infection, pneumonia, congestive heart failure, decreased hemoglobin), number of days in hospital and discharge location (e.g. rehabilitation hospital, nursing home, home) were obtained from the patient's hospital record.
- *Recovery Parameters:* Recovery at 12 months was characterized in terms of survival status, physical functioning, self-rated health, presence of pain in the involved limb, extent of depressive symptomatology and return to prefracture level of physical functioning. Scales in the initial post-surgery interview to assess prefracture walking ability, ADL, IADL and physical

performance were readministered at 12 months with slight modifications to accommodate the telephone interview format. Again a principal component analysis was done to summarize the physical function scales. As before, a single factor emerged, and the associated factor weights were used in computing the 12-month physical function factor score. The global self-health rating referenced to "today", the pain questions and the CES-D were also readministered at 12 months. To accommodate the telephone format, a dichotomous response option, (never = 0; sometimes to always = 1) was used with the 20 CES-D items.

An additional recovery variable was constructed as a count of the number of seven different functional parameters on which the individual had returned to, or surpassed, prefracture levels. The criteria variables included return to prefracture: 1) residence location, 2) use of ambulatory aids, 3) ambulation in the home, 4) ambulation outside the home, 5) performance of self-care, 6) instrumental activities of daily living, and 7) participation in social and recreational activities.

Results

• *Prefracture Health and Functioning:* Although "healthier" hip fracture patients were enrolled, the study sample was not free of pre-existing medical conditions. Patients reported 3.5 (s.d. 2.2) health problems with a greater number of pre-existing medical conditions (x = 6.3, s.d. 3.1) recorded in the hospital record. Prevalent conditions noted in the hospital record included, coronary heart disease (60 per cent), hypertension (53 per cent), osteoporosis (51 per cent), and arthritis (46 per cent).

Most patients, however, reported independence in physical function prior to fracture. Only 19 per cent of the subjects reported requiring any assistance with ambulation. Most sample members (89 per cent) reported they were completely independent in ADL activities and 65 per cent indicated they completed all IADL activities without assistance.

• *Initial Psychosocial Status:* As seen in Table 1, a large proportion of study subjects (57.6 per cent) rated their health on the interview day as fair or poor. This is substantially in excess of that reported in large samples of community dwelling elders.[24,25] The retrospective ratings of health status (just prior to fracture) were much more likely to be positive. Over 50 per cent of the study sample scored 16 or above on the CES-D. Compared to most samples of community dwelling elderly, this proportion is extremely high. For example Berkman, *et al*,[19] report 15 per cent of women 65–74 years of age and 18 per cent of women ages 75+ enrolled in the EPESE study to have CES-D scores of 16 or greater. It is even in excess of the 28 per cent prevalence reported by Billig, *et al*,[26] for the post-surgical hip fracture patients in their case series and the 20–38 per cent prevalence reported for older persons hospitalized for a medical problem.[27,28]

• *Recovery at 12 Months:* Fifteen patients (7.8 per cent) died prior to the 12-month interview. One death occurred during the acute hospital stay and seven others before the six-month interview. This mortality experience is substantially lower than that reported previously,[5,7–9,11,29] even by studies which used restrictive selection criteria similar to ours. For example, Cobey, *et al*,[6] and Jensen, *et al*,[30] report six-month, not 12-month, mortality in comparable samples to be 7.4 per cent, and 5.8 per cent, respectively.

Descriptive statistics for the remaining recovery parameters are displayed in Table 2. Even in this selectively "healthy" sample, most individuals continued to experience a sustained decline in physical function 12 months after fracture. Fifteen individuals were permanent nursing home residents. Another 18.6 per cent were reported to be dependent on a caregiver for assistance in most activities of daily living. Indeed, while approximately 74 per cent indicated at 12 months they walked outside their home, only 21 per cent

TABLE 1—Descriptive Statistics for Selected Psychosocial Variables Measured during the Initial Post-Surgery Interview

		Excellent	Good	Fair	Poor
Global Self-Rating of Health					
% Today, day of interview		7.7	35.6	34.6	22.1

Depression score (CESD):	less than eight	80.0
	eight or more	20.0
Mean	4.14 s.d. 4.3	

reported they could do so without an ambulatory aid. This compares to 81 per cent who walked outside unassisted prior to hip fracture. Moreover, only 28.1 per cent had returned to their prefracture functional status in at least six of the seven functional indicators. Twenty-three per cent had failed to regain prefracture function in at least four criteria.

In contrast to physical functioning at 12 months, the distributions on self-rated health and the CES-D indicate considerable "recovery" in these areas. The proportion rating their health as excellent or good was almost identical to those rating their health status "just before fracture" in this manner. At 12 months only 20 per cent of the sample had elevated scores, ≥ 8, on the modified CES-D scale. (Comparison of post-surgery scores on a dichotomized version of the CES-D with those on the full CES-D showed 93 per cent agreement in classification when cutpoints of ≥ 8, and ≥ 16, respectively, were used.) This proportion is similar to that reported in the total older female sample in the EPESE study[19] and substantially less than that for women in the poorest health status strata.

Predictors of Mortality

The limited number of deaths precluded an extensive investigation of the predictors of mortality. Univariate analyses involved the examination of contingency tables, and the comparison of mean values between survivors and non-survivors on continuous variables using ANOVA procedures. An increased risk of dying was observed for individuals whose cognitive status score was 3 or less, for persons rating their health, referenced to "today", as fair or poor and for those who reported having completed high school or college. There were no mean differences ($p < 0.05$) between survivors and decedents in terms of age, prefracture physical functioning, number of recorded pre-existing health problems, number of diagnoses classified as serious, number of post-surgical medical complications, fracture site, type of fracture repair, or the psychosocial variables.* Individuals who died, however, did have significantly longer lengths of stay in the acute care hospital.

Multivariate analyses used the logistic model. Variables identified as risk factors during univariate analyses were included, along with age, as predictor variables. Adjusted odds ratios (with 95 per cent confidence limits) for each variable in the model tested are shown in Table 3. Only cognitive function following surgery and self-rated health are associated with risk of death. The importance of cognitive function measured after hip fracture for risk of post-fracture mortality has been well documented, even in studies including a similar selectively healthy population.[6,8] Although not with hip fracture patients, other studies have demonstrated an association between self-rated health and mortality.[24,25]

• *Predictors of Recovery among Survivors:* A two-stage analysis limited to study survivors was conducted for five recovery indices: 1) overall 12-month physical function; 2) degree of return to prefracture functional status; 3) self-rated health; 4) pain; and 5) level of depressive symptoms. In the first stage, univariate analyses between measures obtained during the post-surgery period and the recovery indices were conducted. Selected correlation coefficients are presented in Table 4. As expected, age was strongly related to all the physical function indices with recovery more limited as age increased. Predictably, as well, initial measures of health and physical functioning were strongly associated with the com-

parable recovery parameters. To a lesser degree these variables were related to psychosocial functioning at 12 months. With the exception of scores on the extraversion scale and the measures of social connectedness, psychosocial variables measured shortly after surgery were consistently associated with both physical functioning and psychosocial functioning at 12 months. Univariate associations between the recovery indices and treating hospital, length of hospital stay, fracture site, type of fracture repair, number of post-surgical complications, discharge location, ethnic background, prefracture living arrangement and prefracture pain were also examined. Most of these associations were not of importance.*

Multivariate analyses using OLS regression procedures were conducted. Variables shown to be related to a recovery parameter or thought to be a potential confounding variable were entered into the regression equations first; included were: age, years of education, years of employment, number of self-reported conditions, number of medical conditions reported in the hospital record, number of post surgical complications, prefracture physical function score, cognitive status score, days in the acute care hospital, and pain prior to hip fracture. Dummy variables for type of fracture repair, prefracture living arrangement, the presence of pulmonary disease and cancer, and discharge location were also entered. Each psychosocial variable was entered on a second step yielding 35 separate regression equations. Analyses were also conducted in which a best fitting model containing only statistically significant ($p < 0.05$) terms obtained using backward elimination procedures[31] was entered prior to the psychosocial variable. The results of the two analyses were identical; the former are included here. Tables 5 and 6 present the beta coefficients and standard errors for the equations evaluating the importance of post-surgical depressive symptomatology for 12-month physical function and psychosocial status respectively. Data in Table 5 confirm the previously observed importance of age, cognitive status and prefracture physical function for recovery of physical function following hip fracture. As seen in Table 6, except for pre-fracture physical function, these factors are unrelated to psychosocial status at 12 months. The data also replicate previous studies in which pre-existing medical conditions unrelated to cognitive impairments were of limited importance to recovery.[7,11] The type of hip fracture repair and post-surgical complications were also unassociated with recovery at 12 months.

In contrast, the associations between level of depressive symptoms and both the physical functioning and the psychosocial recovery indices stand out. In each case as level of depressive symptomatology following hip fracture surgery increases, outcomes 12 months later are less positive.

Comparable analyses not shown** here revealed the importance of the remaining psychosocial variables to be minimal. Specifically, the two measures of social connectedness and the measure of extraversion were unrelated to any of the recovery parameters. Self-rated health for the reference "just before you fractured your hip" and neuroticism were associated only with the psychosocial outcomes. While

**Findings from these analyses are available on request from the first author.

there were associations between self-rated health for "today" and all five recovery indices, the associations between this health rating and all the recovery parameters except depressive symptomatology disappeared when the CES-D scores were added to the model.

The preceding assumes the presence of linear associations between post-surgery psychosocial variables and the recovery parameters and the absence of interaction effects. These assumptions were systematically evaluated. Analyses of residuals revealed no apparent non-linear associations. As well, none of the tested quadratic terms were statistically significant. Of the more than 100 separate analyses to evaluate the presence of interaction effects, only five achieved a p value < 0.05. Given the number of hypotheses tested, these associations may be due to chance.

Discussion

This study of the "healthier" hip fracture patient demonstrates again that older individuals who are frail have diminished reserves and are thus less able to regain losses in function following hip fracture. Impaired cognitive function as a risk factor for death or incomplete recovery of physical function is especially noteworthy. During study enrollment an experienced nurse researcher had evaluated all individuals as cognitively intact. The observed importance of cognitive status therefore reflects more subtle decrements identified by the inability to correctly respond to specific tasks on the SPMSQ such as naming the past president or subtracting from 20 by threes. Apart from the well known biomedical risk factors, this study demonstrates for the first time the importance of level of depressive symptoms as a determinant of both functional and psychosocial recovery from hip fracture.

Several methodological features of this study make it unlikely that these observed findings simply reflect study artifacts. As noted by Kasl,[13] serious methodological weaknesses of most previous studies of illness course include the inability to identify cohorts at the time of disease onset and to control for pre-existing, prognostically important aspects of health status. These problems have been minimized in this study. Hip fracture is an acute onset injury. Virtually all cases receive immediate medical attention and undergo a surgical repair. Although the initial interviews were conducted following the hip fracture and patient's responses may be affected by her convalescent status, correlations between self-rated health "just before hip fracture" and other retrospective measures such as ADL, IADL and the number of pre-existing medical conditions were substantially greater than those between these variables and self-rated health "today". Conversely, ratings of health today were more strongly correlated with other measures such as CES-D scores or cognitive status that had a post-surgery time reference. Moreover, a substantial amount of information concerning the individuals prefracture medical status was derived from her hospital record and reflected more objective assessments by the physician. Last, inclusion in the multivariate analyses of measures of pre-existing medical status, prefracture physical functioning and cognitive function minimized the possibility that the observed associations between depressive symptoms and the recovery indices simply reflect cross-sectional correlations between these prognostically important variables and depression.

The findings related to depression are in general agreement with those reported by Aneshensel, *et al.*[32] Using longitudinal data from a community dwelling adult sample, they observed illness levels to be temporally related to increased levels of psychological distress and depression to have a smaller lagged effect on subsequent illness levels. They differ, however, from those reported by Casselith, *et al*[33] who found no effect on differential survival or time to relapse among cancer patients due to any psychosocial factors studied including a measure of hopelessness. Casselith's study, however, was limited to individuals with advanced cancers where the inherent biology of the disease may override the influence of any other nonmedical factors. The results observed here were obtained in a patient cohort selected so that the individual's medical status was not likely to overshadow the effects of social or psychological factors.

While confirming the importance of level of depressive symptomatology, the study fails to demonstrate consistent associations between self-ratings of health and personality and achieved recovery. The apparent indirect pathways through depressive symptomatology for health ratings and neuroticism may reflect overlap in these psychosocial factors. Correlation coefficients between initial CES-D scores and neuroticism and health ratings "today" were .626 and .523 respectively. Although introduction of CES-D scores substantially modified the associations between these factors and the recovery parameters, the reverse did not occur. This suggests an importance of depressive symptomatology over and above that shared with either neuroticism or self-rated health. The absence of a detectable effect due to social supports may reflect inadequacies in the measurement of these variables. Only 1.4 per cent of study subjects indicated they had no person they felt very close to; thus most may

have exceeded a threshold distinguishing social isolates from those who are socially connected.

While the analyses reported here provide insight regarding variables that affect subsequent recovery, factors associated with the incidence of depressive symptomatology or the specific process by which recovery is affected have not been addressed. For example, we do not know if elevated post-surgery depressive symptomatology represents deterioration in affective state following hip fracture or an extension of a chronic state of depression. Likewise, we do not know if the importance of post-fracture level of depressive symptomatology is mediated through its effect on participation in a rehabilitation program, on one's ability to mobilize supportive resources or on associated biological factors that affect the capacity for recovery. Analyses of data obtained from informants and at the two- and six-month examinations are in progress and will permit further evaluation of some of these important issues.

Despite unanswered questions, the study findings emphasize the clinical relevance of routine evaluation of depression following surgery in hip fracture patients. Systematic assessment by staff nurses using one of the standard self report measures such as the CES-D or a staff rating scale such as the Raskin Scale[34] would require little time and could substantially reduce undetected depressive symptomatology. Psychiatric referral, when indicated, would permit evaluation and initiation of appropriate treatment. Although further research is required to determine the specific effect on recovery of treatment, reduction of depressive symptomatology alone is beneficial to the individual and is likely to have positive effects on those providing support and caregiving assistance as well. In light of the relatively frequent occurrence of hip fracture and the high prevalence of post-fracture elevated levels of depressive symptomatology, these benefits could be substantial.

ACKNOWLEDGMENTS

This research was supported by grants (R01-AG04095 and R01-AG06827) from the National Institute on Aging, US Department of Health and Human Services.

The authors are indebted to the orthopedic surgeons and staff in the 17 participating Philadelphia hospitals and to the staff at the Institute for Survey Research, Temple University, Philadelphia, Pennsylvania who helped make this research possible.

This work was completed while the first author was an Associate Professor, Department of Family Practice and Community Health, Temple University School of Medicine, Philadelphia, and while she was an Associate Professor, Departments of Psychiatry and Preventive Health, Medical College of Pennsylvania.

Findings from this paper have been reported at the Annual Scientific Meeting of the Gerontological Society of America, Washington, DC, November, 1987.

Delta Omega Society Announces Essay Contest: Open to Public Health Students

Delta Omega, the honorary society in public health, has announced a national essay contest on the topic of "Public Health as Social Justice." Any student currently enrolled in an accredited School of Public Health in the United States is eligible to enter. The deadline for entering contest is *April 15, 1989*.

Within the concept of "public health as social justice," the student may write about any aspect of public health in the United States or anywhere in the world. The essay may be based on empirical research, or literature review or interpretation, or on any other thoughtful approach to the subject selected. Essay length should not exceed 15 pages of text, typed double-space on 8½ × 11 inch paper. References, tables, and figures may occupy any additional five pages.

Winners will recieve cash prizes and certificates from Delta Omega attesting to their awards. First prize is $1500; second prize, $1000; third prize, $500. All three winners will be invited to present their papers during the 117th annual meeting of the American Public Health Association in Chicago, Illinois, October 22–26, 1989. Delta Omega will also contribute to the travel expenses of essay winners.

Selection of the winning essays will be made by a Delta Omega Committee of faculty members from at least three accredited Schools of Public Health. Send all essays by first class mail to:

Preventing Alcohol-Impaired Driving through Community Self-Regulation Training

JOHN K. WORDEN, PHD, BRIAN S. FLYNN, SCD, DARWIN G. MERRILL, MS, JULIAN A. WALLER, MD, MPH, AND LARRY D. HAUGH, PHD

Abstract: A community education program was designed to train the individual drinker to self-regulate his or her blood-alcohol concentration (BAC) below a level of impairment (.05 g/dl or 11 mmol/L). Drink calculators (cardboard wheels and wallet cards) were disseminated to customers of bars and licensed beverage outlets; bartenders and counter clerks were trained to demonstrate use of the calculators and demonstrations were presented in television spots. Program components were evaluated in three matched Vermont communities, one receiving the full community education program, one receiving the TV spots only, and one serving as control. After six months of intervention, a roadside survey of nighttime drivers (N=892) indicated 5.3 per cent fewer drivers with BACs above 0.05 g/dl in the community program group and 1.0 per cent fewer in the TV-only group compared to the control group; however, substantially fewer drivers were found above .00 BAC in either program community than in the control. Drivers reporting heavy drinking and youthful drivers both indicated higher utilization of the materials than did other drivers. Although limited in scale and duration, this study suggests that a community education program can be effective in preventing alcohol-impaired driving. (*Am J Public Health* 1989; 79:287–290).

Introduction

Alcohol-impaired driving remains the leading human cause of highway deaths, despite repeated efforts to deter this behavior through a variety of interventions. In the past, public education has been employed largely to raise awareness of alcohol and highway safety issues and to promote moral persuasion, while most direct interventions to reduce alcohol-impaired driving have focused on external regulation through legislation and enforcement.[1–5] Server interventions show potential for prevention although they have not been evaluated with driving populations.[6,7]

In this study, we have evaluated a community education program which was designed to provide the individual drinker with a cognitive method of self-regulating his or her blood-alcohol level through the use of "drink calculators" which were distributed and demonstrated at licensed alcoholic beverage outlets. In Vermont, such calculators have been used sporadically for a number of years, particularly in school driver education courses, but their use in a concentrated community-wide education program has not been evaluated previously.

Methods

Educational Program

The community education program included: a series of meetings with community leaders; a system through which drink calculators were distributed and demonstrated to community members through licensed alcoholic beverage outlets; and broadcast of public service television spots in which use of drink calculators was demonstrated. The full program was implemented in a single Vermont community with a target population of about 4,000 persons of legal age for both drinking and driving.

Drink calculators are inexpensive devices which provide estimates of blood-alcohol concentrations (BAC) for individuals by body weight and rate of alcohol consumption. Persons using the calculators can estimate the number of drinks they could consume in a given period of time without exceeding the Vermont legal driving limit of 0.10 g/dl BAC (22 mmol/L); estimates are also provided for the number of drinks likely to produce a BAC of 0.05g/dl (11mmol/L), at which impairment of driving skills begins to be perceptible for most people. A drink is defined as one ounce of 100 proof liquor, 12 ounces of beer, or 4 ounces of table wine. Two types of drink calculators were used. Drink calculator wheels are 3″×4″ cards with a rotating wheel mounted. Using the wheel to match body weight and number of drinks consumed provides an estimate of BAC level in a window; a second window provides a time adjustment if these drinks were consumed in a period of more than one hour. The second type of calculator was a simplified wallet-sized card version of this device. Directions for use and motivational messages were printed on the drink calculators.

The distribution-demonstration system for drink calculators was implemented by visits to each retail outlet every four weeks on average throughout the six-month intervention period; visits were scheduled to cover different shifts and were more frequent at the beginning of the period, less frequent later. Service personnel were asked to rehearse demonstration skills and any difficulties were addressed. They were urged to demonstrate and distribute the calculators to customers. Brightly-colored countertop displays which held the calculator wheels were installed prominently at each location.

Logs of these contacts recorded 150 visits to retail outlets. Fifty-three customer service personnel were trained directly in use of the calculator, who, in turn, trained a number of other customer service personnel. Comments from the outlet workers and owners reflected generally good acceptance throughout the implementation period. The calculators were distributed through all 25 retail alcoholic beverage outlets identified in the program community, including: convenience stores (6), restaurants (6), private clubs (5), filling stations (3), lounges (2), supermarkets (2), and one

state liquor store. No licensees refused to participate. About 3,000 drink calculator wheels were distributed through countertop displays, and about 3,000 wallet cards were distributed with purchases of alcoholic beverage. Excess distribution above the target population of 4,000 persons can be attributed to visitor traffic and multiple liquor sales per person.

In addition to face-to-face instruction, use of drink calculators was demonstrated in a series of television public service announcements. A 60-second message featured a well-known race car driver, who was also a local resident, demonstrating use of a drink calculator to his racing crew. Two 30-second messages featured demonstration by popular local bartenders. These messages were broadcast an average of 20 times during each week of the six-month intervention period, primarily during late afternoon and late night hours. The television station was a local network affiliate, with about a 20 per cent share of the audience, whose management undertook the project as a major public service initiative.

Evaluation

The impact of the educational program was evaluated through a controlled quasi-experiment in three Vermont communities. The first community (A) received the full educational program; the second community (B) received broadcasts of the drink calculator television spots but no other element of the educational program; the third community (C) was a measurement-only control.

The three communities were selected from two Vermont counties which had, for the most recent five years, the highest average annual automotive fatality rates (0.33 deaths per 1,000 residents). One of these counties was served by a television station which could not be seen in the second county. Within the former county, the two largest communities were found to provide good demographic matches (see Table 1); the smaller community was designated to receive the full educational program (A) and the larger received television spots only (B). One of two equivalently sized communities in the second county providing the better demographic match was chosen as the measurement-only control site. The two program communities were located about 20 miles apart. The measurement-only community was in a non-adjacent county 80-90 miles from the program communities; a mountain range separates the two areas.

Roadside surveys were conducted in the three communities during April and May 1983 on Friday and Saturday nights between 9 pm and 3 am; police officers stopped all drivers at previously designated locations and visually checked them for signs of drinking. Vermont drivers (N=1,332) were asked to participate in a brief survey administered by the officers; there were no refusals. The officers were not aware of the study design. The survey asked about usual frequency and quantity of alcohol consumption and knowledge of the number of drinks in an hour to reach a BAC of .10 g/dl (22 mmol/L).

TABLE 2—Reported Usual Quantities of Alcohol Consumed by Drivers in Each Study Group at Follow-up Survey

Study Group	Usual Number of Drinks*		
	None	One or Two	Three or More
	%	%	%
Control (N = 311)	19.5	58.8	21.7
TV Only (N = 377)	19.2	60.1	20.7
Community Program (N = 132)	20.5	57.0	22.5

*Number of drinks usually consumed in a one-hour period.

For consistency with program exposure and to obtain the maximum number of respondents, survey participants were assigned to study group by town of residence regardless of the interview location. Participants living outside the boundaries of the community receiving the full educational program but within range of the television station which broadcast the spots were included in the TV-only group; participants residing in other Vermont towns outside of the range of the television signal were included in the measurement-only group.

In October and November 1983, after completion of the six-month educational program, a more comprehensive series of roadside surveys was conducted at equivalent times on weekend nights. Police officers stopped all traffic and, except for a few drivers considered by police to be legally impaired, all Vermont drivers were passed on to a separate team of interviewers. These drivers were assured that, if found to be impaired during BAC measurements given voluntarily, no penalties would be exacted. If drivers and all other occupants of their cars were found to be impaired or otherwise unable to drive they were driven home by members of the survey team. The interview teams collected survey data, including BACs, from all consenting Vermont drivers; BACs of drivers processed by police were also included in the analysis. Of 1,009 eligible drivers, 927 (91.9 per cent) consented to be interviewed; 881 of these 927 (95% per cent) consented to have their BACs measured. Refusal rates by study area were nearly identical. Sixty-nine per cent of the drivers were males, and 53 per cent were age 30 and under; these distributions were nearly identical among the three study areas.

Results

In the baseline survey, there were no differences in the usual drinking patterns reported by drivers or in their estimates of the number of drinks which they could consume within a one-hour period and not be considered legally impaired for driving. Police officers reported that 16.8 per cent of the surveyed Vermont drivers had been drinking: 16.3

0	74.5	80.7	84.4
.01–.04	14.4	9.1	9.7
.05–.09	8.1	5.4	5.2
.10 and Above	3.0	4.7	0.6

per cent were reported in the community program group, 19.3 per cent in the TV-only group, and 14.2 per cent in the control group. As indicated in Table 2, reported drinking patterns also were found to be similar among all three study groups in the follow-up survey.

Program effects were assessed in the follow-up survey using the breath sample measurements of BAC as indicated in Table 3. Only 5.8 per cent of the drivers in the community program had BACs above the level of impairment (.05 g/dl or 11 mmol/L), compared to 10.1 per cent in the TV-only group and 11.1 per cent in the controls. The odds ratio for the community program group staying below the level of impairment relative to the control group was 0.51 (95% CI: 0.24, 1.10); for the TV-only group the odds ratio for BACs below the level of impairment was 0.91 (95% CI: 0.56, 1.45) compared to controls. The odds ratio for a BAC of .00 for the community program group relative to the control group was 0.54 (95% CI: 0.33, 0.91); for the TV-only group this odds ratio was 0.74 (95% CI: 0.49, 0.99). Results from Jonckheere's distribution-free test for ordered alternatives[8] based on recorded BAC levels supported the hypothesized ordering of effects ($p=.03$).

Mediating variables were found to be consistent with these results. As indicated in Table 4, 47 per cent of the drivers residing in the town receiving the full community program said that they had used a drink calculator wheel, 59 per cent said they still possessed a drink calculator wheel at the time of the follow-up survey, 56 per cent recalled seeing the countertop display, and 81 per cent reported seeing the drink calculator wheel demonstrated on television, compared with substantially lower levels of activity in the other two groups.

Driver recall data also indicated that persons at highest risk of alcohol-impaired driving, because they reported usually drinking three or more drinks at a time (i.e., in "an hour or so"), were most likely to be exposed to the drink calculator wheel cards. Table 5 shows higher levels of exposure to program components for high-risk drivers in the town receiving the full community program compared to drivers at lower risk residing in the same town. Similar patterns also exist for high- and low-risk drivers in the TV-only and control groups.

A higher level of exposure to the full range of educational approaches was also reported by youthful drivers (30 years of age and younger) compared to older drivers residing in the town receiving the full community program, as indicated in Table 6. Among youthful and older drivers in the TV-only and control groups, similar exposure patterns were found for drink calculator wheel use. Youthful drivers were more likely to recall the TV spots in the TV-only area than older drivers; no differences were found with regard to the other educational approaches.

TABLE 5—Reported Use of Drink Calculators by Heavy, Light, and Non-drinkers in Community Program Group

Drinker Type	Used Wheel	Used Card
	%	%
Heavy Drinkers* (N = 34)	62	45
Light Drinkers (N = 87)	52	27
Non-Drinkers (N = 31)	23	10

*Reported usually drinking three or more drinks at a time (i.e., in "an hour or so").

Discussion

Questions have been raised about the appropriateness of using drink calculators. For example:

- They are calibrated primarily for a young male population and may give BAC estimates per drink as much as 15 per cent too low for females and the elderly who have different body fat distribution.[9]
- While the dose-BAC relationship may be accurate on average for young males, there is enough personal variation in alcohol metabolism so that some individuals who carefully follow the calculator may still exceed the legal limit if their goal is simply to stay legal.[9]
- The calculators are based on an assumption of a standard "drink" containing about 18 cc (0.6 oz) of pure alcohol. But, as served, many drinks of liquor contain much larger quantities of alcohol, and the distinction between a "standard" drink and a "real" drink for those consuming hard liquor may be too subtle for much of the intended audience.
- Recent reanalyses of epidemiologic and laboratory data indicate that for many people alcohol-related impairment actually begins below 0.5 g/dl (11 mmol/L), although it does not become appreciable until levels of .08 g/dl (18 mmol/L) or higher are reached.[10]

These arguments, although cogent, are insufficient to warrant abandonment of the drink calculator as a useful tool for self-regulation of drinking. Although more women are drinking and drinking heavily as evidenced by crash fatality trends, young males still comprise the vast majority of those who drink heavily and get into trouble with alcohol-impaired driving. These individuals commonly drink enough to reach the maximum legal BAC, and often go far beyond it. If the goal were simply to get these people down to the legal limit, many of them would have to cut their alcohol consumption in half. But the goal of the drink calculator educational program

TABLE 4—Reported Exposure to Drink Calculator Wheels and Cards by Drivers in Each Study Group

Study Group	Used Wheel	Have Wheel	Saw Wheel on Counter	Saw Wheel on TV	Used Card
	%	%	%	%	%

30 and Under (N = 93)	61	68	68	88
Over 30 (N = 66)	27	45	38	71

was to convince individuals that a more sensible approach is to stay below the level of .05g/dl (11 mmol/L).

Roadside survey methods for research purposes, such as those used in this study, have been examined by several courts in relation to Fourth Amendment issues of search and seizure. One opinion by a judge of the US District Court of Minnesota (*Stark vs Perpich, et al,* 1984) suggested methods other than those described in this study. Because US courts are still considering these issues, we as authors feel that we are not in a position to say which of these methods is most appropriate for use in future roadside research.

Limitations of the present study include a six-month intervention and a posttest-only measurement of BAC using three matched communities. Fortunately, there were no differences in the age, gender, and reported drinking patterns of respondents among the three study groups. Proportions of drivers observed by police officers to have been drinking were also similar among study groups, although visual observation is generally imprecise compared to chemical measures.

To maximize usable data collected from nighttime drivers in a small rural state, all Vermont drivers stopped in roadside surveys in the study communities were included by assigning them to study groups based on town of residence and the level of program exposure reaching each town. The modest size of the community receiving the full educational program restricted the number of drivers available for roadside surveys in that area and resulted in a smaller sample than was expected for statistical analysis; results must be viewed with this limitation in mind.

Media exposure was distinctly partitioned by the Green Mountain range to exclude a vast majority of Vermont towns; reported exposure to the TV spots in the control group (22 per cent) was similar to that noted in previous research,[11] and can be attributed to confusion with similar media materials, agreement bias and, to a small extent, true exposure although mobility between control and program communities is limited. It is also interesting to note the increased awareness of the TV campaign in the community program group (81 per cent) compared to the TV-only group (50 per cent) while the channel availability is similar between areas; this may be an example of the supportive roles played by interventions on both the interpersonal and mass media communication levels observed in other intervention studies.[1,2]

The present study is based on the distribution of drink calculators and the training of customer service personnel at alcohol beverage outlets throughout the community. This study has resulted in the development of a community education program involving relatively low cost in personnel and material. The total estimated cost of the six-month program was $3,325: TV-spot production, $1800; materials, $725; personnel and travel, $800.

Results suggest that the community program with mass media support was more effective in preventing alcohol-impaired driving than were the media messages alone, but that the media messages alone also produced a general behavioral effect of deterring the consumption of any alcohol before driving. The primary distinction in results between the groups receiving the full community program and the media intervention alone appeared to be in the proportion of drivers having BACs above the state's legal limit: 0.6 per cent in the community program compared to 4.7 per cent in the TV-only group. This result tends to underscore the role of skills training, since both approaches emphasized the importance of staying below the state's legal limit (as well as the .05 g/dl or 11 mmol/L level of impairment), but the hands-on experience of operating the drink calculators with personal corrective feedback may have served to reinforce the message. Anecdotal reports also reflected social support in the community through the sharing of drink calculators and discussion of how to use them. This self-regulation approach could be included as a component of server interventions described by Mosher.[6]

Most importantly, this type of intervention has stimulated self-regulation by the individual drinker without direct coercion by outside authority. In addition, the known presence of enforcement was an important positive incentive to persons living in all of the study areas. However, this education program has had the distinct advantages of being truly preventive of hazardous behavior and not requiring corrective action by police or the courts. It also was designed to give the individual the skills and social support to develop long-term positive habits which can eliminate the personal risk of driving while impaired by alcohol.

Traffic Safety Effects of Sobriety Checkpoints and Other Local DWI Programs in New Jersey

David Levy, PhD, Dennis Shea, MA, and Peter Asch, PhD

Abstract: We examined the efficacy of three Driving While Intoxicated (DWI) programs in New Jersey from 1980 through 1985, using covariance analysis of county data. Road blocks, the major component of the Strike Force program, were associated with a drop of 10–15 per cent in the single vehicle nighttime crash rate and showed a relatively stable effect over time. DWI Task Force, an education program, was associated with a 6–10 per cent total decline in the crash rate and declining impact over time. SOBER, another education program, was associated with a small effect in the first year and little or no effect thereafter. (*Am J Public Health* 1989; 79:291–293.)

Introduction

Most states and communities in recent years have adopted a variety of programs in an attempt to reduce alcohol-related accidents and fatalities on the highways and roads. Programs have been designed to educate drivers, elicit community support, and strengthen preventive and punitive programs. One of the more controversial efforts is the roadblock or sobriety checkpoint programs, in which drivers are stopped to determine whether they have been drinking while driving. These programs are currently in use in a number of states and under active debate in a number of others.

Since the United States Supreme Court's decision in *Delaware v. Prouse*,[1] checkpoint programs have been subject to the requirement that effectiveness be demonstrated. The Court noted that the "the permissibility of a particular enforcement practice is judged by balancing its intrusion on the individual's Fourth Amendment interest against its promotion of legitimate governmental interest."[2] Yet, little attention has been directed toward evaluating the effectiveness of such policies. Ross, *et al*,[3] found very limited effects in Scandinavian nations, concluding that "there is no evidence of important deterrent consequences." Mercer found that road checks alone were not associated with injury reductions in British Columbia.[4] Two unpublished studies have reported statistically significant reductions of checkpoint programs on traffic deaths and injuries.[5,6]

We report here the results of some studies of the effectiveness of DWI (Driving While Intoxicated) programs in New Jersey. Effectiveness is defined in terms of traffic crash experience, and special attention is devoted to the effects of the Strike Force (checkpoint) program.

Local DWI Programs in New Jersey

Since the early 1980s, state and local programs have been vigorously pursued to reduce the drinking and driving problem in New Jersey. Local level programs include two educational and community support efforts—SOBER (Stay Off the Bottle, Enjoy the Road) and DWITF (Driving-While-Intoxicated Task Force)—and an enforcement and deterrence program, Strike Force (roadblocks). These programs are administered at the county level, with supervision and funding from the state and federal government. Starting dates for programs by county are shown in the Appendix.

The Strike Force program provides overtime funding to police departments on a county-wide basis and uses a system of random roadside checkpoints to examine drivers for possible intoxication. Police direct traffic onto a single lane, where officers speak to the driver and provide drunk driving information materials. Drivers who appear to have been drinking are directed to an area off the roadway for further screening (psychomotor and breath tests).

The checkpoint sites and times are determined by police personnel based on prior analysis of accident and arrest data. Operations are usually conducted on weekend nights and are moved to different sites. Table 1 provides the number of hours worked by police, total costs, number of vehicles stopped, and number of arrests for Bergen County, the first county in New Jersey to implement the Strike Force program and the pilot for other counties. County-wide programs have been supplemented by state roadblocks on state roadways. These were conducted throughout New Jersey from early 1983 in a manner similar to local roadblocks.

Although the Strike Force programs remain small in terms of resources, their impact on public consciousness is important. The county checkpoints have generally been implemented after a SOBER and Task Force program, and the checkpoint programs themselves were publicized on radio and television. The sites are unannounced, but visibility is a prime consideration. Checkpoint trailers with banners were conspicuously parked in the participating county and driven in major areas when not in use. Surveys conducted for the state found awareness of them is close to universal among drivers.

An important part of the deterrence strategy is the informational and consciousness-raising programs, which not only educate citizens but also inform them of enforcement efforts. At a county level, the SOBER and DWITF programs employ pamphlets, public service announcements, seminars for students, and other publicity campaigns about the dangers of drinking and driving, and are directed at educating citizens and eliciting community support. These programs are supplemented by state level efforts and publicity through both the electronic and print media. In 1984, the

SOBER programs in New Jersey (implemented in all but one county by October) had authorized funding of $173,000 and involved 460 press releases in county newspapers, 100 public service announcements on local radio stations, $365,000 worth of advertising on all media, distribution of one million pieces of literature, and 50 billboard advertisements. In that year, DWI Task Force had 640 members in 11 counties, provided two conferences as well as DWI training for police speakers, and was involved in data gathering, lobbying, and monitoring of courts. In 1985, most of the activities of both programs increased by about 10 to 20 per cent.

Methods

Total fatality and crash rates provide a broad measure of traffic safety. To gauge more accurately the effects on alcohol-related events, we focus specifically on single-vehicle nighttime (between 6 pm and 5:59 am) crashes and non-pedestrian fatalities involving a motor vehicle. These measures are regarded as a good proxy for alcohol-related events because of their objectivity, i.e., there is virtually no judgment involved in classifying a single-vehicle nighttime event.[7,8] The drawback of the measure lies in its broadness. Although a preponderance (approximately 70 per cent) of single-vehicle nighttime crashes and fatalities are believed to be alcohol-related, the category includes some events that have nothing to do with alcohol consumption and excludes over events that are alcohol-related. The data were obtained from the New Jersey Office of Highway Safety and are also available from the National Highway Traffic Safety Administration. The fatality data were deflated by total population.

We examined general trends in New Jersey relative to the United States. Using covariance analysis, we also estimated the effects of the different traffic safety programs and other factors on the number of crashes per capita in a particular county. Pooling cross-sectional county data over time, we examined the behavior of traffic safety variables for each of New Jersey's 21 counties over the six-year period, 1980–85, for a sample of 126.

The dependent variable in the covariance analysis was the logarithm of the number of nighttime single-vehicle crashes deflated by county population in the observation year. Upon estimating equations with total fatality and blood alcohol concentration (BAC)-related fatality rates as the dependent variables, all program coefficients had the expected negative signs but were often statistically insignificant. The reason may be that the numbers of fatalities, measured on an annual county basis, are quite small and show considerable volatility over time. Also, BAC tests are not conducted on all fatal victims.

The independent variables in the covariance equations consisted of dummy (i.e., indicator) variables for each county, year, and intervention. The county variables control for the various demographic, highway, and geographic elements specific to a county. The time dummy variables for each year account for general trends in crash patterns. A separate variable was included for each of the three interventions—SOBER, DWITF, and Strike Force—to indicate the presence or absence of each program in each county and year. The value of each variable is zero unless the program was in effect in a given county and year. Then, the value of the variable was defined by the weighting system described below times the percentage of the year in which the program was in effect.

The pattern of influence over time of the programs on the crash rate may vary, e.g., with a significant impact in their first year of operation and then declining effects over time or, alternatively, a slower "start-up" period followed by a greater impact when drivers realize the new efforts at DWI enforcement. We first added dummy variables to the equation for first-year effects, but this yielded a high degree of multicollinearity. Consequently, the first year dummy variables were dropped, but the results from the analysis, along with an examination of the results from a time series intervention analysis that we do not report here,* were used to distinguish a series of weights for the number of years in which the program was in existence.[9,10] The respective weights for the first, second, and third years were 1.0, 0.05, and 0.25 for SOBER, 0.5, 1.0, and 0.5 for DWITF, and 0.5, 1.0, and 0.75 for Strike Force. The weights on the SOBER variable reflect an abrupt first-year effect that declines sharply thereafter. In contrast, the Strike Force Program effect was gradual, increasing and remaining relatively stable after the first year, whereas the DWI Task Force effect occurred gradually but declined more sharply after the second year.

We included lagged values of the dependent crash rate variable in some equations to control for the "inherent" safety characteristics of various counties and for correlation in the error term over time for each county. The problem of uneven error terms arising from populations varying across counties and over time (i.e., heteroscedasticity) is treated by a method adapted from Cook and Tauchen.[11]

Results

Preliminary evidence on traffic fatality and crash rates is provided in Table 2. In New Jersey between 1980 and 1985, total crash rates rose by 8 per cent while total fatality rates fell by 16.2 per cent. During the same time period in New Jersey, single-vehicle crash rates fell by 18.6 per cent and fatality rates fell by 27.9 per cent, both falling considerably more than total fatality rates. For the United States, consistent data were available for fatality rates, but not crash rates. For the US between 1980 and 1985, all fatality rates fell by 18.3 per cent, 2.1 per cent more than the New Jersey rates, and single-vehicle fatality rates fell by 24.5 per cent, 3.4 per

*A Box-Jenkins analysis, allowing for a flexible shape of the intervention variable, was conducted for Bergen County, using monthly data for 1980–85. The SOBER and DWITF programs exhibited declining effects over time, while the effects of the Strike Force program were found to increase over time.

TABLE 2—Fatality and Crash Rates, by Year, per 1000 Population

Year	NJ Total Crash Rate	NJ Total Fatality Rate	NJ Single Vehicle Nighttime Crash Rate	NJ Single Vehicle Nighttime Fatality Rate	US Total Fatality Rate	US Single Vehicle Nighttime Fatality Rate
1980	29.9	0.1521	4.13	0.0649	0.2248	0.0871
1981	29.6	0.1569	4.03	0.0583	0.2147	0.0813
1982	29.9	0.1428	3.91	0.0562	0.1894	0.0748
1983	28.6	0.1248	3.35	0.0493	0.1818	0.0694
1984	29.7	0.1227	3.25	0.0404	0.1872	0.0696
1985	32.3	0.1275	3.36	0.0468	0.1836	0.0657
% Change 1980–85	8.03	−16.2	−18.6	−27.9	−18.3	−24.5

cent less than the comparable New Jersey rates. The fall in New Jersey's single-vehicle nighttime rates relative to the state's all-fatality rate and relative to the US single-vehicle nighttime fatality rate would suggest that New Jersey was effective at deterring alcohol-involved traffic crashes. However, a number of other influences may have contributed, such as other statewide policy changes in New Jersey (including two increases in the minimum legal drinking age and stricter court penalties for drinking and driving).

Equations explaining single-vehicle nighttime crashes at the county level are presented in Table 3. The county and time dummy variables are not reported here (since they are not of direct interest) but these variables were in almost all cases significant at standard levels. Equation #1 (without the lagged dependent variable) and equation #2 (with the lagged dependent variable) have high explanatory power (in terms of the R-squared), and all program variables have the expected negative sign. The coefficient for the Strike Force variable indicates that the program at its peak reduced the single-vehicle nighttime crash rate by between 10 per cent [in equation #1, with a 95% confidence interval (CI) = −0.175, −0.015] and 15 per cent [in equation #2, with 95% CI = −0.25, −0.040]. Based on the weighting scheme, the peak effect is reached in the second year and then gradually declines. The DWITF program reduces the crash rate between 6 per cent [95% CI = −0.162, −0.33] and 10 per cent [95% CI = −0.175, 0.053], but this effect declines more quickly over time. The effect of SOBER is near zero and insignificant, but approaches significance using a one-tailed test in equation #1.

Discussion

The estimated program effects, particularly for the checkpoint program, may be understated since programs in one county may have "spill-over effects" in terms of driving behavior in other counties. Not only do the estimated program effects fail to directly take into account any spillover in terms of crashes avoided in nearby counties, but may also bias downward the estimated effect in the county implementing the program. Drivers may avoid drinking and driving in a county without a checkpoint program, because they must pass through a participating county to get to their destination. Furthermore, state checkpoints at the time of the county programs may have lowered crash rates statewide.

TABLE 3—Covariance Analysis of Single-Vehicle Nighttime Crash Rates[a,b,c]

Independent Variables	Equation 1	Equation 2
Lagged Dependent Variable		3.37 (1.48)
SOBER	−0.025 (−1.223)	−0.009 (−0.246)
DWITF	−0.096* (−2.85)	−0.061 (−1.06)
Strike Force	−0.095* (−2.33)	−0.143* (−2.71)
Adjusted R-Square	0.98	0.93

b) By county, 1980–85.
c) t-statistics in parentheses.
*indicates statistically significant from zero at the 0.01 level (one-tailed test).

The findings suggest that a checkpoint or "roadblock" program such as New Jersey's Strike Force reduces single-vehicle nighttime crashes. Besides the results reported here, separate time-series analyses for one of the demonstration counties in New Jersey strongly support this conclusion, indicating program effects of greater than a 20 per cent reduction in the single-vehicle nighttime accident rate at their peak. The effects of programs oriented toward publicity and education about the dangers of drinking and driving are less impressive; even here, however, we suspect that judicious, perhaps sporadic, use of such campaigns may have temporary beneficial impacts. However, it may well be that the effectiveness of the checkpoint program itself depends partly on the publicity that accompanies its implementation.[4]

Blood Alcohol Tests, Prevalence of Involvement, and Outcomes Following Brain Injury

Jess F. Kraus, MPH, PhD, Hal Morgenstern, PhD, Daniel Fife, MD, MPH, Carol Conroy, MPH, PhD, and Parivash Nourjah, MSPH

Abstract: We collected data on all residents of San Diego County, California who were hospitalized for or died from a brain injury in 1981. The objectives were to assess the frequency of blood alcohol concentration (BAC) testing and the associations of BAC prevalence with the external cause of the brain injury and case outcome. We found that high BAC levels were most frequent among brain-injured subjects between the ages of 25 and 44 and among those subjects involved in motor vehicle crashes and assaults. Contrary to expectations, injury severity and hospital mortality were inversely related to BAC level, controlling for other predictors. We believe that these inverse associations might be due to differential rates of BAC testing by severity. Among brain-injured survivors with more severe injuries, however, we found that BAC level was positively associated with the prevalence of physician-diagnosed neurological impairment at discharge and with the length of hospitalization. (*Am J Public Health* 1989; 79:294–299.)

Introduction

The scientific literature on alcohol and motor vehicle crashes points to high risk of crash involvement when alcohol is consumed.[1] However, less information is available on many questions about alcohol use and injuries. For example, which subgroups of injured motorists are blood-alcohol-tested and, by extension, are the published findings representative of all those injured?

A related question is the relation of alcohol to the occurrence of some types of nonmotor-vehicle-related injuries. Although the association between blood alcohol concentration (BAC) and risk of injury is well established for motor vehicle crashes,[1] general aviation crashes, drownings, snowmobile crashes, and violence,[2–4] there are less well established linkages between alcohol and injuries from falls and from injuries at work or during some recreational activities.

A third question involves the role of alcohol in the outcome of injury. Animal studies[5–15] have demonstrated a variety of physiological effects of alcohol (ethanol) on injuries. In humans, however, the findings are equivocal. Some reports[16,17] suggest that intoxicated persons are somehow protected from serious injury; other studies suggest that intoxication leads to more severe injuries.[18–20] An important public health aspect of these findings is whether the physician's ability to establish accurate diagnoses for persons with neurological injuries[21–25] is compromised by the presence of alcohol.

This report describes BAC testing among a cohort of San Diego County, California residents who were brain-injured in 1981 and examines the rate of BAC testing, the proportion of positive BAC test results, the relation of BAC level to brain injuries from various external causes, and the relation between BAC level and injury outcome.

Methods

Members of the cohort were residents of San Diego County, California who were hospitalized (or died) in 1981 due to brain injury. Specific details of the study design, study region, case ascertainment, and methodology are reported in detail elsewhere,[26–28] and certain relevant points are summarized here.

For purposes of this study, brain injury is physical damage to, or functional impairment of, the cranial contents from acute mechanical energy exchange exclusive of birth trauma. Information was ascertained on persons with autopsy evidence of brain injury who died at the injury scene or were dead on arrival at an emergency room and on persons admitted to a hospital with physician-diagnosed brain injury.

Brain-injury cases were identified from emergency room and inpatient hospital records of acute care general hospitals in the county; all coroners' records in San Diego County and the adjoining counties of Imperial, Orange, and Riverside; all death certificates (regardless of cause or place of death) for residents of San Diego County; a survey of all nursing homes and extended care facilities in San Diego County; and reviews of the nine major hospitals in the three counties bordering San Diego County. Autopsy and coroners' records were obtained for all relevant fatalities.

For people surviving until hospital admission, the Glasgow Coma Scale (GCS) was used to assess the level of brain-injury severity.[29] This scale was used consistently in all San Diego County emergency rooms during 1981. For a few patients, a verbal response was not recorded (e.g., because of intubation), and it was assumed to be unimpaired if eye and motor response were unimpaired. For a very small number (less than 1 per cent) of severely injured patients for whom the GCS was not assessable, the medical chart was examined thoroughly and all relevant clinical information was used to judge brain-injury severity. The GCS used for these analyses was measured upon arrival at the emergency room.

Patients admitted with a GCS of 8 or lower were defined as *severe* cases; those with a GCS of 9 or greater were defined as *moderate* if they had a hospital stay of at least 48 hours and either a GCS below 13, an abnormal computerized axial tomography (CAT) scan, or brain surgery. All other cases were termed *mild*. These categories and criteria are consistent with those suggested by Jennett and Teasdale[29] and Levin, *et al.*[30]

Overall injury severity was defined using the 1980 revision of the Abbreviated Injury Scale (AIS) which assigns

a severity level from 1 to 6 to each injury.[31] The Injury Severity Score (ISS) assigns an overall measure of injury severity based on AIS scores.[32,33] Injuries are assigned to six body regions (face, head and neck, chest, abdomen, extremities, and general), and the ISS is calculated as the sum of the squares of the highest AIS values for three separate regions. A patient's ISS is a good measure of the risk of death from injuries, and this predictive power is improved by age-adjustment.[32,33]

Rates of neurological limitations were derived for all moderately or severely brain-injured persons admitted to a hospital. These rates were adjusted for age, gender, and injury severity at the time of emergency room treatment. Neurological limitations included only physician-diagnosed deficits or limitations at the time of hospital discharge.

Persons under the age of 15 have been excluded from the analysis because they were not generally tested for blood alcohol by either hospitals or coroners in 1981.

Blood alcohol samples were generally obtained while the person was in the emergency room, and results were abstracted from the hospital record or the coroner's report and were not based on police reports. Most hospitals and coroners used a gas chromatographic method to determine blood alcohol concentration.

The effects of BAC and other factors on injury severity and hospital mortality were estimated and tested with multiple logistic regression.[34]

Results

Of the 3,358 new cases of brain injury identified, 709 were under the age of 15 and excluded from the analyses.

BAC Testing

Forty-four per cent of 2,649 brain-injured persons age 15 and older were BAC tested. The overall BAC testing rate was higher for males (49 per cent) than for females (30 per cent) and varied by age. BAC testing was lowest in young adults (32 per cent) and those over age 64 (36 per cent), and it was highest for those aged 40–49 and 60–64 (52 per cent and 55 per cent, respectively).

Those dead on arrival (DOA) at the hospital had a BAC testing rate of 99 per cent, and those dead at the scene (DAS) of injury and taken directly to the county morgue had a BAC testing rate of 93 per cent. Persons admitted to a hospital with severe, moderate, or mild injuries had BAC testing rates of 61, 54, or 30 per cent, respectively.

BAC testing rates also varied by external cause of the injury (Figure 1). Persons with brain injuries from firearms had a BAC testing rate of 87 per cent, compared with 47 per cent from motor-vehicle crashes, 43 per cent from assault, 33 per cent from falls, and 22 per cent for all other external causes combined. Since the comparison of these BAC testing rates may be confounded by age, gender, and severity of brain injury, the external cause-specific rates were adjusted (by the direct method) for these factors. As shown in Figure 1, the differences in BAC testing rates among injury types (defined by external cause) were reduced substantially after adjustment, especially for firearm injuries.

BAC testing rates were highest for brain-injured pedestrians and lowest for bicyclists struck by a motor vehicle (Table 1). BAC testing rates were higher for drivers than for passengers, and the rates increased with severity of brain injury for all road-user categories. These BAC testing rates did not change appreciably when adjusted for age and gender.

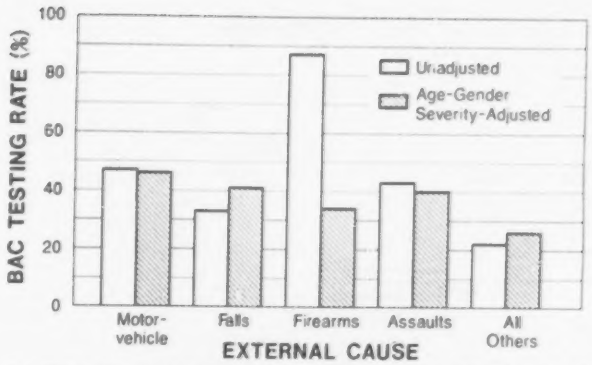

FIGURE 1—The per cent of brain-injured persons tested for BAC, by external cause of the injury: A comparison of results unadjusted and adjusted for age, gender, and injury severity

Proportion with Positive BAC

Of the 1,155 BAC-tested cases, 493 (43 per cent) had a negative result, 98 (8.5 per cent) had a BAC of 1 to 99 mg% (.22–21.70 mmol/L), 257 (22 percent) had a BAC of 100–199 mg% (21.71–43.20 mmol/L), and 307 (27 per cent) had a BAC of 200 mg% (43.42 mmol/L) or higher. Driving with BAC of 100 mg% (21.71 mmol/L) or higher is either an offense per se or presumptive evidence of driving under the influence (DUI). Driving with lower BACs can also result in DUI charges in most states. Generally, the proportion of those tested who had positive tests decreased beginning at about age 45 (Table 2). One-third of those aged 25–64 who tested BAC positive had a blood-alcohol level of 200 mg% (43.42 mmol/L) or higher.

Higher proportions of mildly brain-injured persons who were tested had positive BAC tests, compared with those with moderate or severe brain injuries or those who were DOA at the emergency room or taken directly to the coroner's office (Table 3).

The proportions with a positive blood-alcohol result varied by external cause of the injury. Two-thirds of those tested who were brain-injured from motor vehicle-related causes had a positive BAC; lower prevalences were observed for assaults (60 per cent), falls (44 per cent), firearms (35 per cent), and all other causes (42 per cent). These differences may be confounded by severity of injury and age (Tables 1 and 2); hence, the overall proportion with a positive BAC and the proportions at each BAC level were adjusted for these

TABLE 1—Per Cent of Brain-Injured Subjects Who Were Tested for Blood Alcohol Concentration (BAC), by Injury Severity and Road-User Category, San Diego County, California, 1981

Road-User Category	Injury Severity			
	Mild	Moderate/ Severe	DOA*	Total
Occupant	33	63	99	46
Driver	36	68	100	50
Passenger	29	56	96	39

factors. The unadjusted results did not differ much from the adjusted results for persons injured in motor vehicle crashes or falls (Figure 2) but did differ from the adjusted estimates for persons injured from firearms or assaults. Among tested subjects with a positive BAC, those injured by firearms tended to have a lower BAC level and those injured by falls had a higher BAC level than did other injured subjects.

Results of BAC testing by road-user category among motor vehicle-related brain injuries are given in Figure 3. The proportion with a positive BAC is between 60 and 70 per cent for all road-user categories, and the proportions are five to nine times higher for persons with BAC levels of 100 mg% (21.71 mmol/L) or higher than for those with BAC levels less than 100 mg% (21.71 mmol/L).

BAC results for brain-injured victims of motor vehicle crashes are given in Table 4 by injury severity and road-user category. Fifty-nine per cent of these tested subjects had BAC levels greater than or equal to 100 mg% (21.71 mmol/L), and this proportion was higher for drivers of cars, vans, or light trucks than for brain-injured passengers in these vehicles or for motorcyclists, pedestrians, and bicyclists. In each road-user category, the proportion having a high BAC level (≥100 mg% [21.71 mmol/L]) was greater for those with mild brain injuries than for those having more severe injuries.

Work-Related Brain Injuries

One hundred fourteen of the 2,649 members of the eligible cohort sustained a brain injury while engaged in work-related activities. Of the 21 subjects who were BAC-tested, 17 had a negative result, but all four subjects with a positive result had a BAC level of 100 mg% (21.71 mmol/L) or higher.

TABLE 3—Per Cent of Tested Subjects with a Positive BAC and the Per Cent at Each Level, by Injury Severity, San Diego County, California, 1981

	Blood Alcohol Concentration in mg% (mmol/L)			
Severity of Brain Injury	1–99 (.2171–21.70)	100–199 (21.71–43.20)	200+ (43.21+)	Positive BAC (≥1 mg% [.2171])
Mild	7	27	37	71

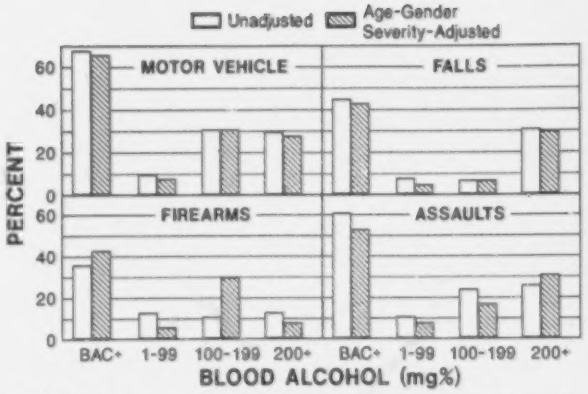

FIGURE 2—The per cent of brain-injured subjects with a positive BAC and the per cent of each BAC level, by external cause of the injury: A comparison of results unadjusted and adjusted for age, gender, and injury severity

BAC Testing and Possible Selection Bias

The effects of five factors on brain-injury severity (moderate or severe versus mild) are presented in Table 5. Results of multiple logistic regression show that the probability of sustaining a moderate or severe injury is positively associated with firearm injuries and age and inversely related to blood-alcohol level. This latter finding is consistent with the results of the crude (unadjusted) analyses shown in Tables 3 and 4. Although this inverse association with BAC level is in the direction opposite to that which one might expect, this finding may have resulted from differential rates of BAC testing by injury severity. It is conceivable, for example, that persons having a mild brain injury might not be tested for blood alcohol unless there was obvious intoxication while most persons with more severe injuries get routinely tested, regardless of actual BAC level. This explanation of selection bias is consistent with our data, which showed that while only 30 per cent of mild brain-injured persons were tested, 70 per cent of these persons had a positive BAC; yet, of the 74 per cent of moderate or severe injuries that were tested, only 45 per cent of these had a positive BAC. Thus, the apparent protective effect of alcohol seen in Table 5 (risk odds ratio of 0.6) could be the result of differential testing rates by severity.

The potential impact of differential BAC testing by severity is illustrated by the hypothetical data in Table 6. As shown in the upper panel, we have assumed that while there is no association between actual BAC level and BAC testing among all persons with moderate and severe injuries in the total source population (OR = 1.00), there is a positive association among persons with mild injuries (OR = 4.51). Using only the data for BAC-tested persons, as shown in the lower-left panel, we find that a positive BAC appears to protect against a more severe injury (OR = 0.35), which is the crude result actually obtained in this study. Using the hypothetical data for all persons in the source population, however, we see in the lower-right panel that there is no association between BAC level and injury severity (OR = 1.00). Thus, the inverse association observed in this study can be explained by selection bias caused by differential rates of BAC testing. Although the illustration in Table 6 is based on certain hypothetical data, we believe the underlying assumptions about BAC testing are quite plausible.

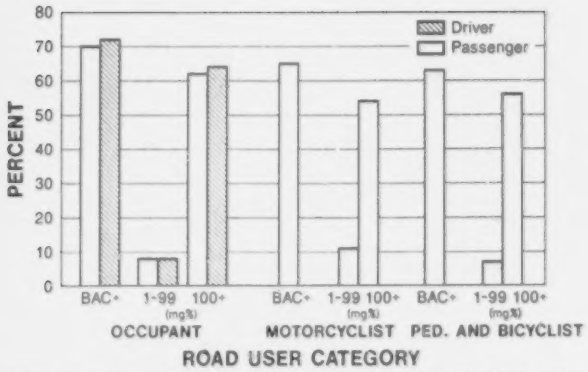

FIGURE 3—The per cent of motor vehicle-related brain-injured subjects with a positive BAC and the per cent at each BAC level, by road-user category and driver/passenger status

Effects on Hospital Mortality

Of the 1,155 persons who were tested for BAC level, 807 were admitted to a hospital alive because of their injuries and 86 died while hospitalized, an overall case-fatality rate of 11 per cent. The estimated effects of four factors on hospital mortality, based on multiple logistic regression, are given in Table 7. While the effects of injury severity and age are positive, as expected, the apparent protective effect of a higher BAC level on case fatality is similar to its effect on injury severity (Table 5). Thus, as with the previous finding, the observed effect of BAC level on case fatality might have been biased by differential rates of BAC testing (Table 6).

In Table 8, the adjusted BAC effect on hospital mortality is compared for various restrictions of the study population according to injury severity. Note that the apparent effect

TABLE 4—Per Cent of Tested Subjects with a Positive BAC and the Per Cent of Tested Subjects with a High BAC Level (≥100 mg% or 21.71+ mmol/L) among Brain-Injured Victims of Motor Vehicle Crashes, by Injury Severity and Road-User Category, San Diego County, California, 1981

Road-User Category	Severity of Brain Injury			
	Mild	Moderate/ Severe	DOA[a]	Total

[a]Includes those dead on arrival at the hospital or taken directly to morgue.
[b]Includes passenger cars, vans, pickup trucks.
[c]Includes three passengers.
[d]Includes only those involved in a motor-vehicle collision.
*Based on fewer than 10 BAC-positive cases.

TABLE 5—Estimated Adjusted Effects of Five Factors on Injury Severity (Moderate/Severe vs Mild): Results of Multiple Logistic Regression (n = 1155)

Factor	Risk Odds Ratio (ROR)	95% CI (ROR)
Age	1.54*	(1.21, 1.96)
BAC Level (mg%)	0.60**	(0.53, 0.68)
Cause of Injury		
Firearms	9.92	(3.69, 26.7)
Falls	0.67	(0.54, 0.83)
Assaults	0.44	(0.36, 0.55)
Other***	1.00	

*Corresponds to an age difference of 25 years.
**Corresponds to a BAC level difference of 100 mg%.
***The reference category of which 78% are motor vehicle injuries.

(ROR <1) decreases (i.e., ROR becomes closer to one) as the logistic regression analysis is restricted to more severe injuries. This finding is also consistent with our previous interpretation of possible selection bias due to differential rates of BAC testing since most severe injuries are routinely tested.

Other Outcomes

Physician-diagnosed neurological impairments were recorded for all brain-injured patients admitted to a hospital with moderate or severe injuries *and* discharged alive from an acute care hospital. Rates of neurological limitations were higher among those patients with positive BAC levels (46 per cent) than for patients with negative BAC levels (32 per cent). The difference in rates was 14 per cent (95% CI = 2, 26). As shown in Figure 4, however, the elevated risk of neurological impairment (adjusted for age, gender, and severity) seems to be restricted to persons with a BAC level of 100 mg% (21.71 mmol/L) or greater.

TABLE 6—Hypothetical Illustration of Selection Bias Due to Differential BAC Testing in Estimating the Effect of BAC Level on Injury Severity

A. BAC Testing

Actual BAC Level	Moderate/Severe Injury			Mild Injury		
	BAC Test	No Test	Total	BAC Test	No Test	Total
Positive	275	95*	370*	384	444*	828*
Negative	332	115*	447*	161	840*	1001*
Total	607	210	817	545	1284	1829
OR = 1.00				OR = 4.51		

B. Brain Injury Severity

BAC Level	Observed among Tested Subjects			Hypothetical Data in Total Source Population (Tested and Untested)		
	Moderate/ Severe	Mild	Total	Moderate/ Severe	Mild	Total
Positive	275	384	659	370	828	1198
Negative	332	161	493	447	1001	1448
Total	607	545	1152	817	1829	2646
OR = 0.35 (95% CI = 0.27, 0.44)				OR = 1.00		

*These numbers are hypothetical but consistent with the assumptions about BAC testing that are stated in the text.

TABLE 7—Estimated Adjusted Effects of Five Predictors on Hospital Mortality among Hospitalized Patients: Results of Multiple Logistic Regression (n = 808)

Predictor	Risk Odds Ratio (ROR)	95% CI (ROR)
Age	2.90*	(1.70, 4.93)
Sex (Male/Female)	1.25	(0.85, 1.83)
BAC Level (mg%)	0.67**	(0.49, 0.92)
Injury Severity		
Severe	28.72	(10.4, 79.1)
Moderate	4.26	(1.46, 12.4)
Mild***	1.00	

*Corresponds to an age difference of 25 years.
**Corresponds to a BAC level difference of 100 mg%.
***The reference category.

Length of hospital stay did not differ by BAC level on admission. A similar result was found when persons who died in the hospital were excluded from the analysis. Yet length of stay was positively associated with BAC level among patients with severe injuries. Almost 80 per cent of those with a positive BAC test were hospitalized two weeks or longer, compared to 62 per cent of those with no blood alcohol on hospital admission. There was little association between length of stay and BAC level among patients with mild or moderate brain injuries.

Although the effect of BAC level on length of stay was observed for patients with severe brain injuries (i.e., GCS <8), it is still possible that this effect might have been confounded by amount or type of brain damage. Nevertheless, we found no evidence for such residual confounding in our data since the mean Injury Severity Score (ISS) in patients with severe injuries was similar for patients with positive and negative BAC levels.

Discussion

Findings from this study show that over one-half of all brain-injured persons who are seen in a hospital emergency room are BAC-tested; but until BAC testing for all hospital-treated injured persons is instituted, unbiased estimates of actual BAC frequency and its effects among brain-injured persons will not be possible.

We found that the rate of blood alcohol testing among brain-injured persons in San Diego County is related to type and severity of the injury. Thus, the inverse association observed between BAC level and injury outcome (severity and mortality) is very likely biased due to differential rates of BAC testing, especially among persons with less severe injuries (Table 6). Indeed, the adjusted estimate of the BAC effect on hospital mortality is reduced appreciably when the analysis is restricted to severe injuries only (Table 8).

TABLE 8—Comparison of Adjusted BAC Effect on Hospital Mortality by Restriction of the Study Population According to Injury Severity: Results of Three Multiple Logistic Regressions*

Severity Levels	No. Subjects	No. Deaths	Risk Odds Ratio (ROR)**	95% CI (ROR)
Mild, Moderate and Severe	808	88	0.67	0.49, 0.92
Moderate and Severe	263	87	0.80	0.61, 1.05
Severe Only	141	80	0.82	0.62, 1.09

*Each BAC effect estimate is adjusted for age, sex, and severity level (where needed).
**Corresponds to a BAC level difference of 100 mg%.

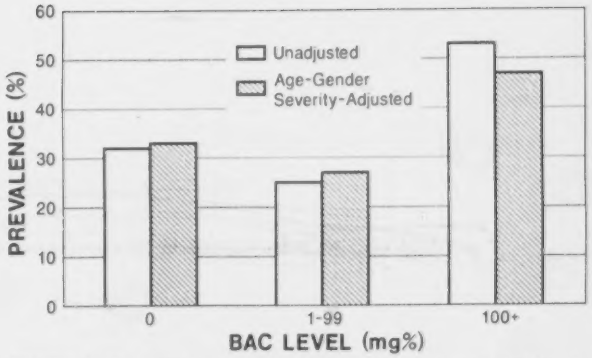

FIGURE 4—The prevalence (%) of physician-diagnosed neurological impairment at hospital discharge among moderately and severely brain-injured patients discharged alive from an acute care hospital, by BAC level: A comparison of results unadjusted and adjusted for age, gender, and injury severity

The ability of clinicians to diagnose and assess the nature and severity of brain injuries[35] influences treatment, particularly in persons with specific types of lesions.[16,23] Information on blood alcohol concentration is an important medical management tool and should be available on all persons seen for brain injuries in hospital emergency rooms.

There are at least two reasons why routine BAC testing of hospital emergency room patients who have been injured has not been more widely practiced:

- The principal function of emergency room activity is to determine whether the patient should be admitted to the hospital or discharged. If BAC testing is essential to the physician's decision on disposition of the patient, blood specimens are taken. Even if the patient shows signs of alcohol use (e.g., breath odor) the BAC test often may not be requested if it would not materially assist in determining disposition.
- Requesting a BAC test in the emergency room may have legal implications. That is, some physicians might not request a BAC test if the result, once recorded in the medical record, could lead to a legal problem for the patient. Because the prevailing practice in most emergency rooms of Level I or Level II trauma centers is to order a computerized tomography scan for any patient with altered consciousness, the value of a blood alcohol test is diminished. If there is altered consciousness and no overt evidence of alcohol use, however, a blood test may be requested to rule out alcohol in the diagnosis.

What remains for future research is to study the advantages and disadvantages of knowing blood alcohol level among possible brain-injured patients in the emergency room. Because blood samples are taken from patients with serious brain injuries who arrive at an emergency room for treatment of injuries, BAC testing could easily become routine even when there has been a substantial delay between injury and initiation of treatment. An alternative approach might be a quick, inexpensive, and noninvasive breath test to differentiate alcohol from ketones, as in diabetic ketosis.

The most perplexing finding from this study relates to outcomes from brain injury with and without alcohol involvement. Despite the animal evidence from observational and controlled laboratory studies,[5–15] the evidence that alcohol

affects injury outcome is not conclusive. Ward and colleagues[16] reported that in a large series of patients having many different types of injuries, mortality was lower in patients who had been drinking than in those who had not been drinking. Huth *et al*,[17] found that hospital course and late outcomes were unaffected by the patient's blood alcohol level. Luna and associates[18] found that although injury severity in critically head-injured motorcyclists was not related to alcohol intoxication, mortality was twice as high in intoxicated patients as in nonintoxicated patients. The investigators suggested that severe brain injury and acute ethanol intoxication acted in a synergistic manner to prevent the patient's homeostatic injury response. Results from these studies may also have been biased due to differential rates of BAC testing, as in this investigation.

Although injury severity and case fatality were inversely related to BAC level, the rate of neurological limitations among moderately or severely brain-injured survivors was positively related to BAC level. In addition, for those with severe brain injuries, controlling for age and total body injury severity, brain-injured subjects with positive blood-alcohol concentration had a longer duration of hospital stay. Since BAC testing rates were highest in the most seriously injured group, these observed effects are less likely to have resulted from selection bias. On the other hand, a physician's knowledge of alcohol use (or blood alcohol) at the time of injury might conceivably influence reporting of neurological limitations, which might be related to chronic alcohol use. But this alternative explanation is not very likely among younger patients with brain injuries.

It was not possible with the information available to identify chronic alcoholics from occasional drinkers among the brain-injured cohort. Hervé, *et al*,[20] reported recently on injury mortality and blood alcohol levels in France. Their data seem to suggest that chronic alcoholics had a higher mortality rate than did non-alcoholics, occasional drinkers, or non-drinkers, controlling for age and overall injury severity level. The possible interaction of long-term, heavy alcohol use and the acute intoxication at the time of an injury has not yet been investigated.

Risk of Fatal Rollover in Utility Vehicles Relative to Static Stability

LEON S. ROBERTSON, PHD

Abstract: The risk of fatal rollover of utility vehicles per 100,000 registered vehicles relative to cars during 1982–87 was strongly correlated to the static stability of the vehicles. Distance between the center of the tires divided by twice the height of center of gravity explained 62 per cent of the variation in fatal rollover rates where rollover was the first harmful event. Statistical controls for 20 major risk factors indicated no correlations that would deflate the correlation between stability and rollover. Low stability utility vehicles roll over more often on the road suggesting that the lateral force of turning is often the tipping force. (*Am J Public Health* 1989; 79:300–303.)

Introduction

The sales of utility vehicles, sometimes called multipurpose vehicles, have increased substantially in recent years. In 1986 some 725,000 were sold in the United States compared to 132,000 in 1982.[1] Questions regarding the stability of these vehicles were raised in 1980 when the Jeep CJ-5, the Ford Bronco, and the Chevrolet Blazer were found to have rollover rates per registered vehicle much higher than passenger cars. These utility vehicles also had lower static stability than a sample of cars, as measured by the distance between the center of the tires divided by twice the height of center of gravity, usually expressed as T/2H.[2] T/2H of utility vehicles range from 1 to 1.2 while that of the vast majority of cars is above 1.2 and range as high as 1.6.[2,3]

The principle of static stability can be illustrated easily with a section of 2×4 lumber. Placed on its two inch side, it is easily tipped over by a force from the side, but placed on its four inch side, it tends to slide rather than tip over given the same force. The higher the weight from the ground relative to the width of the bottom decreases the stability. In a moving vehicle, the lateral force generated in a turn provides a potentially tipping force.

Studies of utility vehicles in the early 1980s confirmed the markedly higher rollover rates of utility vehicles relative to cars but did not attempt to correlate the rates with static stability.[4–6] A recent study found that, for the four utility vehicles and 11 cars for which static stability had been published, the fatal rollover rate per registered vehicles during 1981–84 in the US decreased exponentially in relation to static stability. The correlation was almost perfect; static stability explained 96 per cent of the variation among those vehicles. Static stability was not correlated to fatal crash rates where rollover did not occur.[7]

In response to a petition from Congress, the National Highway Traffic Safety Administration (NHTSA) gathered static stability data on a number of vehicles and conducted a study of single-vehicle crashes, mostly nonfatal, in three states. Static stability explained 86 per cent of the variation in rollover per cent.[3]

Since the relative risk of fatal rollover crashes in a number of recently marketed utility vehicles has not been studied, this communication reports an analysis of fatal rollover crashes in relation to static stability of these vehicles, as well as the older ones, during 1982–87 in the US. Other known risk factors were examined as possible confounding factors.

Method

The available data on static stability of utility vehicles that have been measured are presented in Table 1. In some cases, only one vehicle was measured. In the instances of multiple measures, the major intravehicle variation occurs in the vehicles that have the same name for different sized versions, namely Blazers and Broncos. It is possible that some of these vehicles were misidentified at time of measurement or in transmitting the information to NHTSA. In the analysis here, the median value rather than an average is used to minimize the effect of atypical measures or erroneous vehicle identification.

The data on fatal crashes of the utility vehicles in which an occupant of the vehicle died were extracted from the Fatal Accident Reporting System (FARS) data tapes for the calendar years 1982–87.[8] These tapes contain information on virtually every fatal crash in the US with the possible exception of some that occurred in late 1987 and had not been reported when the tape for that year was released. Vehicles were identified by decoding vehicle identification numbers that contain codes specifying makes and models. For comparison, all crashes in which an occupant died in rollovers and nonrollovers were also counted.

Data gathered from state motor vehicle administrations by R.L. Polk Company were used to count registrations by make and model during 1982–84.[9] Since R.L. Polk data do not include vehicles registered in Oklahoma, vehicles that crashed in Oklahoma during the years that registrations were counted from that source were eliminated from the analysis.

TABLE 1—High, Low and Median Stability Ratios (T/2H) Measured by Various Sources

The regression coefficient of yearly changes in vehicle registrations by vehicle age was used to estimate scrappage of vehicles as they aged in 1985–87 (per cent change = −0.28 × vehicle age, $R^2 = 0.31$). For new vehicles, vehicle sales data[1,10] were used to count registrations. The monthly sales were multiplied by the number of months to the end of the study period and the sum of these months was divided by 12 to obtain registered years.

The rate of fatal rollover as "first harmful event," defined as the event causing the initial damage to the vehicle or occupants,[8] was examined for each vehicle with sufficient registrations relative to that of all cars. Log odds of the relative risk was used to establish confidence intervals.

If instability contributes mainly to rollover, there should be little increased risk of nonrollover fatal crash rates of vehicles with low stability ratios. Therefore, the relative risk of nonrollover fatal crashes of the utility vehicles relative to cars was examined as well.

Direct controls for the potential confounding effects of driver's characteristics or driving environment could not be applied since the necessary data on use were unavailable. Maximum potential confounding was estimated for 20 factors by measuring the relation between each factor and stability within the group of fatal rollover crashes. Factors unrelated to stability could not confound the effect of stability on risk. Expressed mathematically:

$$C\ L/H = RL/RH = b(S)$$

where L = low exposure to a risk factor
H = high exposure to a risk factor
C = constant ratio of risk from low to high risk situations
RL = fatal rollovers in low risk-factor situations
RH = fatal rollovers in high risk-factor situations
S = Stability value for a given vehicle
b = the slope of the correlation

This equation says that the ratio of rollovers in low relative to high-risk-factor situations is a function of the ratio of exposures in those situations times the relative risk ratio C. For other risk factors to explain the correlation of static stability to rollover rates, there must be a positive correlation of one or more of the ratios of rollovers by risk factor with static stability. Therefore, if b has a positive value, then the risk factor is a potential confounding factor that inflates the stability effect. A near-zero correlation indicates that the risk factor could not have produced a spurious correlation of stability and rollover rates. A negative correlation implies that the stability effect may be deflated by confounding. The ratio of numbers of rollovers in low relative to high-risk situations were examined for 20 major, known risk factors, including any alcohol and alcohol above the legal limit in the states where 80 per cent or more of fatally injured drivers were tested.

Results

Vehicles that had fewer than 100,000 registered years during the study period—the Montero, Trouper, and Wrangler—were eliminated from the analysis. Table 2 presents the analysis of the relative risk of fatal rollover as first harmful event in relation to the all-car rate, 1.3 per 100,000 registered vehicles. The Jeep CJ-5 was 19.7 times more likely to experience a fatal rollover per registered vehicle than a car. The Jeep CJ-7, the pre-78 Ford Bronco, and the Ford BroncoII were clustered in the range of 10 to 12 times the fatal rollover rate of cars. Another cluster with a relative risk three to six times that of cars included the Dodge Ramcharger, the 1982–87 Ford Bronco, the General Motors large and small Blazer/Jimmys and the Suzuki Samurai. The lowest relative risk was 1.3 for the Jeep Cherokee and the lower confidence limit for that vehicle was the only one within the range of all cars.

The relation of the first-harmful-event rollover rate to the stability ratio, T/2H, displayed in Figure 1, is striking. The higher the stability the lower the fatal rollover rate. In a linear model, 62 per cent of the variation among vehicles was accounted for by the stability ratio. The regression coefficient of −86 (95% confidence interval = −39 to −132) suggests that increasing the stability ratio by one-tenth decreases the annual fatal rollover rate by an average of about 9 per 100,000 registered vehicles, within the range of stability ratios of the vehicles in the study.

Since vehicles sometimes roll over subsequent to other "first harmful events," the correlation of stability ratios with rate of rollover as "most harmful event" was also examined. The pattern was similar to that in Figure 1 but the rates were higher.* The regression coefficient of −143 (95% CI = −64 to −222, $R^2 = 0.61$) suggests that an increase in the stability ratio of one-tenth would decrease the annual most-harmful-event rollover rate in which an occupant dies by an average 14 per 100,000 vehicles, again within the range of stability ratios of these vehicles.

The risk ratios for utility vehicle occupants relative to car occupants of fatal crashes without rollover are displayed in Table 3. Eight of the 10 vehicles had risk ratios less than one relative to cars, two with upper bound less than one. Only the Jeep CJs had confidence intervals above and outside the range of the all-car rate and their relative risk ratios were less than two.

The relation between stability and driver or environmental characteristics is shown in Table 4. None of the 20 risk factors was substantially positively correlated to T/2H. The on-road/left-road correlation was negative, indicating that lower stability vehicles more often rolled over on the road rather than after leaving the road, as plotted in Figure 2.

The other environmental risk factors were unrelated systematically to vehicle stability. No driver factor was correlated systematically to vehicle stability, including age, gender, presence of alcohol or illegal alcohol, invalid licenses, prior crashes, prior suspensions or convictions for driving while intoxicated, speeding, or other offenses.

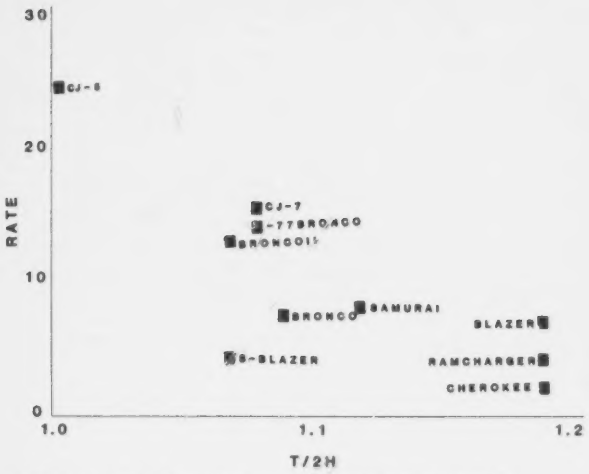

FIGURE 1—Fatal Rollover Crashes per 100,000 Registered Vehicles

Discussion

These and previously published data leave little doubt that vehicle stability is the primary factor contributing to the higher fatal rollover crashes in utility vehicles than cars. The result is consistent with well-known principles of physics. The nonrollover fatal crash rate of utility vehicles, which is caused by factors other than stability, is similar to that of cars. None of the powerful predictors of fatal crashes generally—rural roads,[11] lack of light,[12] prior driving record,[13] alcohol,[14] age and gender[15]—were related to stability ratios in such a way as to be confounding factors.

The only risk factor related to stability is the on-road/off-road factor. The fact that the less stable vehicles more often roll over on the road is consistent with the hypothesis that many more of them roll over because of the lateral force of turning alone, or perhaps even occasionally by very strong side winds, rather than going over embankments or ramping, which is much more likely to happen off the road rather than on it.

The possibility that some combination of risk factors contributes to the correlation of stability and rollover is extremely remote. The factors most strongly predictive of fatal crashes generally, such as age and gender, are known to be independently correlated to the risk of a fatal crash.[12] While all of the risk factors examined do not occur independently of one another, the fatal rollover crashes are distributed among the categories of the factors in such a way that high enough concentration in some important combination, which is also in turn strongly combined with low stability vehicles, is not possible given the lack of correlation of stability with the factors considered separately.

Despite widespread publicity in 1980 regarding the rollover propensity of the Jeep CJs, several manufacturers have subsequently introduced new vehicles with low stability. The lack of a perfect correlation of rollover rates with static stability suggests that some manufacturers of later model vehicles may have partially offset the effect with better than average suspension systems or other vehicle characteristics moderating the tendency of lower stability vehicles to

TABLE 3—Relative Risks of Fatal Nonrollover Crashes to Occupants of Utility Vehicles Relative to the All-Car Rate

tip over in turns. Nevertheless, the static stability is a strong predictor that could be used to set standards for vehicles.

The National Highway Traffic Safety Administration has denied petitions to address the problem.[16,17] The agency's main justification for its inaction was that static stability is a continuously distributed variable and that to choose a required point would be arbitrary. It also said that it is prohibited by law from banning a class of vehicles which such a standard would do. If standards could not be set on continuously distributed factors, however, there would be no standards for blood alcohol concentration and head injury criteria. Since a standard for static stability could be met by simply widening the distance between the center of the tires and/or lowering the center of gravity, such a standard would not ban a class of vehicles. Furthermore, one utility vehicle with stability in the range of that of passenger cars had a rollover rate similar to passenger cars.

Another issue is whether the vehicles now in use should be recalled and modified to reduce rollover risk. Smaller diameter tires would reduce the height of the center of gravity on the high-risk vehicles. It may also be possible to weld some weight along the undersides of the vehicles to make them more stable. Given the risk and the fact that each cohort of these vehicles will be in use an average of more than 10 years, a testing program seems indicated to evaluate the effect of such modifications on stability.

4th National Environmental Health Conference, June 20–23

The Center for Environmental Health and Injury Control of the Centers for Disease Control; the Agency for Toxic Substances and Disease Registry; and the Association of State and Territorial Health Officials have announced the Fourth National Environmental Health Conference will be held June 20–23, 1989, in San Antonio, Texas. The primary audience is federal, state, and local health and environmental officials and physicians and the environmental community.

The theme of the 1989 conference is "Environmental Issues: Today's Challenge for the Future." The objectives are to: address the environmental insults that have the greatest importance to public health; review topical scientific findings; and discuss prevention strategies. Plenary sessions will be on radon; medical, municipal, and hazardous waste; air pollution; lead in the environment; and dioxin. Twenty workshops will be held on topics of interest to states, academic institutions, and federal agencies including health assessments at NPL (national priorities list) and RCRA (Resource Conservation and Recovery Act) sites, emergency responding, radiation, birth defects, risk communication, indoor air pollution, and respiratory disease.

Category 1 Continuing Medical Education credits for physicians only are being offered for designated sessions sponsored by the Centers for Disease Control, and accredited by the Accreditation Council for Continuing Medical Education.

For further information, contact either Lewis Webb (404/488-4700) or Dr. John Andrews (404/488-4682) or the Centers for Disease Control or Peter McCumiskey (404/488-4682) at ATSDR, all in Atlanta, GA.

Evaluation of a Community-Wide Incentive Program to Promote Safety Restraint Use

ROBERT D. FOSS, PHD

Abstract: A program was designed and evaluated to determine the feasibility of implementing an incentive campaign to promote safety restraint use, primarily among children up to age 13. During a five-month period, community residents were eligible to win monthly prizes and a grand prize by buckling up all automobile occupants when driving. Systematic monitoring of traffic and a telephone survey indicate that the program was minimally effective, reaching the attention of only about half the families with children in the community despite extensive advertising. Effects of the program on seat belt use closely paralleled airing of radio announcements, appear to have been confined primarily to children under age four, and tailed off somewhat after the initial response. (*Am J Public Health* 1989; 79:304–306.)

Introduction

It has now been a decade since the first state law was passed mandating the use of safety seats to protect children from injury or death in automobiles.[1] All 50 states and the District of Columbia now have enacted child safety restraint laws and many of the earliest laws have been strengthened. Several defects notwithstanding,[2] the laws appear to have been modestly successful in increasing the number of very young children who ride properly buckled up, and in reducing injuries and fatalities.[3,4] Yet according to ongoing, nationwide observation of child safety restraint use, only 27 per cent and 17 per cent of 3-year and 4-year-old children, respectively, (most of them born after child safety seat laws were enacted in their states) rode buckled up in 1985.[5]

A number of experimental studies have found that short-term educational interventions do not reliably affect whether parents will buckle up their children beyond the first few months of life,[6–9] if that.[10,11] Nor is there any substantial evidence that the availability of seat loaner/rental programs, by themselves, serves to substantially increase the number of young children who ride buckled up.[12]

It has been suggested that rewarding safety restraint use provides an alternative way to increase the use of safety restraints.[13,14] Incentive programs have been developed in a number of communities,[15–17] based on the notion that many individuals who can be induced to buckle up repeatedly over a period of time, by the offer of a chance for material reward, will continue to buckle up out of habit even after rewards cease. Several careful studies have documented impressive short-term increases in adult safety belt use as a result of such incentive programs, both in limited populations and on a community-wide basis.[15,18,19]

Although most incentive programs have focused on adults, it has been demonstrated that both elementary and nursery school children can be induced to buckle up as well by carefully designed incentive programs.[14,20,21] One of the primary advantages of incentive programs is that they can be extremely cost-effective when focused on an entire community, rather than a small, delimited population such as a workplace, school, or day care center.[13] Adopting a community focus, however, requires somewhat different tactics, which could conceivably render an incentive program far less successful.

A community-wide incentive program, with several crucial differences from small scale incentive programs, was designed and implemented. In contrast to earlier studies, this program: focused on a wide age range (birth through age 12); offered only a small chance of winning monthly prizes and a grand prize, rather than a substantial chance for small rewards; did not maintain high visibility monitoring of a fixed location, but instead involved unobtrusive, temporally and geographically diffuse monitoring for prize eligibility; and was conducted (except for the evaluation component) by a small group of volunteers. All these elements may reduce effects of an incentive program, but are necessities in community-wide programs, especially those that are not part of a well-financed research project. Perhaps the largest obstacle to implementation of a community-wide project is effectively bringing it to the attention of a substantial proportion of the public, a task that is much more easily managed in programs designed for geographically confined populations.

Method

The program, conducted from mid-September through mid-February in a university community with a nonstudent population of approximately 45,000, was designed to provide incentives for parents to buckle up both their children and themselves, as well as to influence school age children directly. The incentives were prizes in a monthly drawing of license numbers for cars whose occupants had been spotted buckled up at some time during the month. Specifically, any car containing at least one child judged to be under the age of 13 that was spotted by a member of the local Child Passenger Safety Council, in which all occupants were buckled up, was entered in a monthly lottery. Each time a car that met the criterion was spotted, its license number was recorded and entered, so the more often everyone buckled up, the greater the likelihood of the car's owner winning a prize. On the tenth day of each month a winner was randomly selected from the license numbers of those cars that had been recorded during the preceding 30 days. Unless they won a prize, members of the target population had no way of knowing whether their behavior had been detected.

The program was advertised by two weeks of radio advertisements (30-second spots, six times daily), a newspaper article and a supportive newspaper editorial as the contest began, in addition to approximately 80 large posters (42.5 cm × 57.5 cm) placed prominently throughout the community. In addition, letter-size flyers were distributed monthly to several thousand elementary school children announcing the prize for the month as well as the grand prize. On two occasions these distributions were accompanied by a

letter to children emphasizing the importance of seat belt use, explaining how they might win, and encouraging them to pressure their parents to buckle up and to be sure siblings also were restrained. Flyers were also posted monthly next to the larger posters. Several hundred flyers also were mailed directly to parents of young children <5 years old who had participated in two earlier telephone interview studies concerning safety restraint use.

Monthly prizes ranged in value from $50 to $200. The grand prize, for which every car observed with everyone buckled up at any time during the five-month period was eligible, was a family vacation to a Florida theme park. All prizes were donated by local merchants. Some radio time was donated by local stations; the remainder of the ads were purchased with funds donated by community members to support efforts of the local Child Passenger Safety Council. Although a state law mandating proper restraint of children up to age five was in effect at the time of the study, it was not enforced, nor had it ever been enforced or advertised since its enactment over three years earlier.

Prior to the contest, throughout its duration, and for some time thereafter, data on safety restraint use by children in the community were systematically collected by paid, trained observers. None of these observers were involved in spotting cars for prize eligibility. This ongoing monitoring activity was conducted for research purposes tangentially related to the incentive program. Observations were normally made, weather permitting, from 10 am to noon on Saturday mornings and from 3–5 pm during the week. Darkness and frigid weather reduced observation periods to one hour from November through February. Several additional late morning, mid-week observation periods were scheduled during Christmas break, when a reasonable number of older children could be observed. Observers were stationed at several locations that were selected for community representativeness and maximum visibility of automobile occupants. Observers recorded the restraint use, estimated age, and seating position of all children in automobiles that passed their vantage points. Although most observers probably were aware of the contest, they were not told that they were evaluating its effects and were unlikely to have drawn that conclusion on their own, since observations had been conducted for about 10 months before the contest began.

Results

School age children were analyzed separately from children under age six.

Infants and Preschoolers

From a baseline of 27 per cent prior to the contest, restraint of children under age six in vehicles rose immediately and dramatically in response to the early publicity announcing the contest, reaching 38 per cent during September and 43 per cent during October (Table 1).

About one month after initial radio advertising of the contest was discontinued, restraint use began to decline. It settled back to the baseline rate briefly, about 16 weeks after the contest began, and 13 weeks after media reminders of the contest had stopped. In response to this decline, an additional two weeks of radio ads were aired a few weeks prior to the end of the contest. Restraint use again increased, to 33 per cent during the final week of the contest. During the five-month incentive period, restraint use averaged nearly 10 per cent above the pre-incentive period. During the seven-week period immediately following the contest, a consistent rate 5 per cent above the pre-incentive period was maintained.

Because restraint use varies widely by age among preschool age children,[22–24] effects of the incentive program were examined for separate age groups. As Figure 1 illustrates, children above the age of four appear to have been affected initially, but the effect drops off later. Because age was estimated, these results must be interpreted with caution. Nonetheless, the pattern of sharp decline in use, and difference in responsiveness to incentives between infants and older children is unmistakable.

School-Age Children

Restraint use by children ages six through 12 years riding in rear seats (i.e., use of lap belts) is difficult to measure reliably in moving vehicles. Consequently, data are presented only for front seat occupants and there are fewer observations than for infants and preschoolers. The pre-incentive use rate (10 per cent) increased to 16 per cent during the second month of the contest, but declined again. During the final month of the contest, in concert with renewed radio advertising, the use rate peaked at nearly 20 per cent, declining again to 13 per cent during the seven weeks following the contest.

Although the incentive campaign required adults as well as children to be buckled up to qualify for prizes, safety belt use among adult front seat occupants hovered around 11 per cent before, during, and following the contest period.

Telephone Survey Results

To determine awareness of the incentive program, telephone interviews were conducted shortly after the campaign with 40 randomly selected parents of children from four of the schools where flyers had been distributed. Despite extensive advertising, only 59 per cent of the respondents were aware of the contest. Among those parents who did know of the incentive program, 35 per cent reported learning about it from the radio spots. The next most effective method was direct distribution of flyers to school children, with 26 per cent of

TABLE 1—Proportion of Children Restrained Before, During, and After Incentive Period by Age

	0–5 years (N)	Difference from Baseline (95% CI)	6–12 years (N)	Difference from Baseline (95% CI)

parents reporting that they learned about the contest from the flyers. Although 91 per cent of those who knew about the contest knew they needed to buckle up to win, only 18 per cent accurately reported the specific but crucial requirement that everyone in the car had to be buckled up. Almost nobody could identify the month the contest began, the month it ended, or any of the monthly prizes.

Discussion

The alterations needed to direct an incentive campaign to an entire community appear to attenuate the effectiveness of this approach. In the current case, creating and maintaining awareness of the program was a major problem. During periods of extensive radio advertising, response to the program was clear, although unspectacular. The fact that few people could identify information that was clearly printed on thousands of flyers distributed in the community and advertised repeatedly further emphasizes the difficulty of implementing an incentive campaign in a general population. At the least, it suggests that requirements must be extremely simple.

It appears that radio ads aired over a short period of time in a small community were an effective way to advertise the program. The modest resurgence in response to renewed ads suggests that it may be possible to sustain a moderate, community-wide increase in the rate of safety restraint use long enough for habitual use to be established. It remains to be seen whether this finding is generalizable to a more populated area. Th question of whether heavy advertising over a several month period may lose its effectiveness must also be addressed.

The marked differences in response to incentives to buckle up by various age groups point once again to the second, third, and fourth years of life as a pivotal time in safety restraint use.[13] These children, who are least likely to be restrained, are also the most difficult to reach with a programmatic effort. A similar age-differentiated effect was found for the state child restraint law a few years earlier in this same community.*

The third and fourth years of life are a time when children are in transition from near total control by parents to a point where they engage in many behaviors, including safety seat/belt use, substantially in accordance with only their own wishes. Although the body of literature on child development is huge, we know virtually nothing about how or whether this age-related increase in the autonomy of children is implicated in the distressingly high prevalence of nonuse of safety restraints by older preschool aged children. Nor has our understanding of parent-child interaction or of effective child-rearing been tapped. Such matters clearly must be understood if we are to deal effectively with safety belt use among children. Instead of merely demanding that parents protect their children, through laws mandating safety belt use, the solution to this problem probably lies in the development of techniques to encourage and assist parents to develop the habit of safety belt use by their children at a very early age.

Evaluation of the Efficacy of Simulation Games in Traffic Safety Education of Kindergarten Children

LISE RENAUD, PHD, AND SAMY SUISSA, PHD

Abstract: Using a simulation game designed to teach children to obey certain traffic safety rules, an experimental study was conducted with 136 five-year-old children in four Quebec schools. Within each classroom, subjects were randomly divided into four groups: three intervention groups and one control group. Each of the experimental groups was subjected to a different intervention with outcome measured using three instruments related to attitudes, behavior, and transfer of learning of pedestrian traffic safety. Results suggest that simulation games including role-playing/group dynamics and modeling/training can change attitudes and modify behavior in the area of pedestrian traffic safety in children of this age. (*Am J Public Health* 1989; 79:307–309.)

Introduction

In Quebec, a Canadian province with 6 million inhabitants, the 1984 pedestrian injury rate in 5- to 9-year old children was 162.4/100,000 as compared to 67.1 for the population as a whole.[1] The prevention of such accidents involves legislation, engineering, education, or a combination of these. One possible way of preventing accidents is to teach children to obey certain rules of safety. This study evaluates a simulation game as an effective educational strategy in reaching this goal.

A "simulation game" is a simplified and dynamic model of a real or hypothetical system where players, following a set of rules, compete or cooperate in order to win. We used a simulation game, developed by la Régie de l'Assurance automobile du Québec (Automobile Insurance Board) and the Ministère de l'Education, and a proposed component of Quebec's preschool program.

Research on attitude and behavior modification suggests that role-playing group dynamics and model-training are effective means of triggering change in attitudes or behaviors and that they can be used effectively in simulation games. Role-playing group dynamics is more important in attitude change,[2–7] while modeling-training appears to have a stronger impact on behavior.[8–12] Simulation is a good strategy for effecting changes of attitudes or behaviors in psychosocial situations and produces transfer of learning.[13–16] Transfer of learning is defined as: "The extent to which the learning of an instructional event contributes or detracts from subsequent problem solving or learning of subsequent instructional events."[17] For example, knowledge in one sport may be transferable to another sport, typewriting skills may be transferred to a computer keyboard, etc.

The objective of this study was to determine the effect of certain elements within a simulation—namely role playing/group dynamics, and behavior modeling/training—on the attitudes and behaviors and transfer of learning of five-year-old pedestrians with respect to traffic safety rules.

Methods

We used an experimental scheme based on the post-test-only control group design because a pre-test might have provided participants with knowledge which would influence their reaction to the instrument.

The four schools participating in this study are representative of the schools in Montreal, a principal city in the province of Quebec. Within each school, two kindergarten classes composed of five-year-old children were selected. This age group was chosen because the traffic safety program is designed for kindergarten children. Within each class, children were randomly allocated to each of four groups: three intervention and one control.

The experiment consisted of two three-hour sessions. The first involved the presentation of the simulation games and the administration of attitude and behavior tests. The second session, conducted 10 days later, included only the administration of the transfer of learning test.

Intervention

We used three simulation games with the same learning content: traffic safety for the pedestrian. Each of the three experimental interventions included different elements within the same basic simulation game structure. Basically, the game simulates a part of a town complete with streets and sidewalks (dimensions: 1.22m × 2.44m). Five-year-old pedestrians "walk through" the miniature streets using finger puppets drawn on the backs of their hands.* The three simulation games are:

- *ATTITUDE:* This simulation game includes role-playing and group dynamics elements and is intended to primarily affect attitude change. Personal (verbal and behavioral) interactions and a loose scenario centered around a specific situation constitute the unique features of this simulation game.
- *BEHAVIOR:* This simulation game includes modeling and training elements and is intended to change behavior. Observation of a model, behavioral imitation, and feedback constitute the unique features of this simulation game.
- *ATTITUDE AND BEHAVIOR:* This simulation game includes role-playing, group dynamics, modeling and training elements and is intended to alter both attitude and behavior. The features from the other two simulation games constitute the simulation game.

Measurements

Three measurement instruments were used.* The instruments were simple since the experiment involved five-year-olds.

*More details on the simulation game and measurement tests are available from the authors.

Attitude measurements were based on methods developed by Gochman.[18] Specifically designed for children, they measure the behavioral component of attitudes, i.e., the individual's predisposition to act when faced with the object of an attitude. This predisposition is determined by the child's perception of pedestrian vulnerability to traffic accidents, and the child's perception of the degree of danger that traffic in general presents to the pedestrian. Photographs are used to identify health risks. The children's perception of risk (health dimension) and their recommendations to avoid risk (prevention dimension) are measured. Ten photographs, validated by a jury of three researchers and tested in another group of children, were used to measure the perception of risk.

Behavior measurements were based on methods developed by Whalen and Rolf.[19] Children use images to show how they would act in a given situation. The measurement instrument is composed of a picture of a road, a series of questions, and stickers to be used in answering the questions.

Transfer of learning was measured using the methods developed by Haynes.[20] The transfer of learning was measured by observing children's reaction to a quasi-real life model of traffic risks set-up in the gymnasium. Only the lateral transfer of learning, which is defined as any facilitation of learning resulting from possession of previous knowledge in a related field, was studied. A trained observer notes the presence or absence of a predetermined selected set of behaviors using a scoring sheet specifically designed for the behavior being observed.

Analysis

The reliability of each measurement instrument was evaluated using Chronbach's alpha. Pearson's correlation coefficient was used to associate the two different dimensions of the attitude scale, as well as to verify that attitude, behavior and transfer of learning were not related.

The four intervention groups were compared, for each of attitude, behavior, and transfer of learning, using a three-way analysis of variance model (main factor: intervention; co-factors: school, sex). Since school was considered a random factor, a mixed model was used. Interactions and co-factors were tested and dropped from the final analysis if deemed insignificant. Multiple comparisons of confidence intervals were obtained using Tukey's method.

Results

The attitude measure had a range of 0–3. Each of its two dimensions, health and prevention, had a reliability coefficient of $\alpha = 0.89$ indicating good reliability. These dimensions were highly associated (Pearson correlation coefficient, $r = 0.61$), suggesting that they constitute two aspects of the same construct. The reliability coefficient for the global score of the behavior test (range: 0 to 5) is $\alpha = 0.41$ (the small number of items (5) in this test substantially affects the reliability coefficient). The reliability coefficient for the transfer of learning test (range: 0 to 31) is $\alpha = 0.85$.

Little association was found between the two dimensions of attitude and the other study variables (behavior and transfer of learning) (correlation of health dimension of attitude and behavior, $r = 0.20$; prevention dimension of attitude and behavior, $r = 0.23$, health dimension of attitude and transfer of learning, $r = 0.30$; and prevention dimension of attitude and transfer of learning, $r = 0.26$).

With respect to the primary hypotheses under study, the statistical assessment is made separately for each of the three components of outcome. In each case, sex was not significant and was removed from the analysis. In addition, the interaction between the intervention and the school factors was negligible and therefore removed from the analysis.

TABLE 1—Summary Statistics of Attitude, Behavior and Transfer Scores by Intervention Group

Variables	Intervention			
	Control	Attitude Simulation Game	Behavior Simulation Game	Attitude/ Behavior Simulation Game
ATTITUDE (range 0–3)				
Sample size	33	35	33	34
Mean ± SD	1.3 ± 0.7	1.9 ± 0.7	1.8 ± 0.6	2.0 ± 0.7
BEHAVIOR (range 0–5)				
Sample size	34	35	33	34
Mean ± SD	4.0 ± 1.1	4.9 ± 0.2	4.3 ± 0.8	4.5 ± 0.7
TRANSFER (range 0–31)				
Sample size	30	33	32	33
Mean ± SD	7.9 ± 3.7	8.7 ± 3.1	10.4 ± 2.1	10.1 ± 2.3

NOTES: Attitude simulation game = simulation game including role-playing/group dynamics.
Behavior simulation game = simulation game including modeling/training.
Attitude/behavior simulation game = simulation game including role-playing/group dynamics, and modeling/training.
Control = no intervention.

Attitude

Table 1 indicates that the means of the attitude test are similar between the intervention groups but quite different from those of the control group. Table 2 shows a clear difference between each of the three intervention groups and the control group on the attitude test. The group which used the simulation game involving role-playing/group dynamics, and modeling/training performed only slightly better than the two other intervention groups.

Behavior

The control group mean is lower than the three intervention group means. The means of groups using the simulation game that included attitude triggering elements (attitude and behavior simulation and attitude simulation) are

TABLE 2—Pairwise Mean Differences of Attitude, Behavior and Transfer Scores among Interventions for Pre-selected Contrasts

Variables	Difference Between Mean Scores	95% Confidence Interval
ATTITUDE		
Attitude simulation game vs control	0.60	0.13, 1.07
Attitude/behavior simulation game vs control	0.72	0.26, 1.21
Behavior simulation game vs control	0.52	0.05, 1.00
BEHAVIOR		
Behavior simulation game vs control	0.33	−0.57, 1.24
Attitude/behavior simulation game vs control	0.50	−0.40, 1.40
Attitude simulation game vs control	0.94	0.05, 1.84
TRANSFER		
Attitude simulation game vs control	0.83	−1.83, 3.48
Behavior simulation game vs control	2.48	−0.20, 5.15
Attitude/behavior simulation game vs control	2.22	−0.44, 4.88

NOTES: Attitude simulation game = simulation game including role playing/group dynamics.
Behavior simulation game = simulation game including modeling/training.
Attitude/behavior simulation game = simulation game including role playing/group dynamics, and modeling/training.
Control = no intervention.

superior to the means of the groups exposed to behavior triggering elements (Table 1). In addition, there is a significant difference in performance between the group having used the game containing attitude triggering elements and the control group (Table 2).

Transfer of Learning

The three intervention groups obtained a higher mean than the control group on the transfer of learning test (Table 1). However, as shown in Table 2, the confidence intervals of the differences are wide. The group that participated in the simulation game containing behavior triggering elements (modeling and training) scored slightly higher than groups exposed to simulation games containing attitude triggering elements.

Discussion

All three intervention groups did better than the control group on all three tests (attitude, behavior, and transfer of learning). More specifically, the findings on attitude confirm empirical research related to attitude modification (theories of reinforcement,[2–4] group dynamics,[8,9] dissonance,[6,7] and inoculation.)[5] However, contrary to indications from empirical research on attitude modification, the behavior triggering elements (modeling/training) were found to be as effective as the attitude triggering elements since exposure to any of the three simulation games resulted in good traffic safety attitude.

Use of behavior triggering elements in a simulation game appeared to motivate cautious behavior (Table 1). This finding supports those of Bandura[10,11] as well as those of Parcel and Baranowski[12] which indicate that the presence of behavior triggering elements is sufficient to modify behavior. Attitude triggering elements (role-playing/group dynamics) were more effective in motivating cautious behavior than behavior triggering elements themselves (Table 2). The main difference noted is between the subjects using games containing essentially attitude triggering elements and the control group. These results coincide with the studies of Insko,[21] Zimbardo and Ebbesen[22] which indicate that the presence of attitude triggering elements is necessary and sufficient to modify behavior.

Finally, review of the literature on simulation games[13–16] suggests that they are inherently conducive to transfer of learning because they give learners a chance to test their knowledge and skill in an environment similar to reality. Although our findings support those of empirical research (all experimental groups scoring higher than the control group on transfer of learning), our results apply only to five-year-old children and to a simulation game on traffic safety situations. Therefore, they should not be generalized to other populations or to triggering elements other than those contained in the simulation games studied.

In summary, although, our findings do not allow us to conclude that the simulation games will transfer these good traffic safety habits to a real pedestrian situation, we can state that simulation games using triggering elements may serve as an effective educational strategy in modifying attitudes and behavior concerning traffic safety.

Childhood Injury Deaths: National Analysis and Geographic Variations

ANNA E. WALLER, BA, SUSAN P. BAKER, MPH, AND ANDREW SZOCKA, MPH

Abstract: Twenty-three causes of injury mortality in children ages 0–14 in the United States were analyzed by age, race, sex, and state of residence for the years 1980–85. Motor vehicles caused 37 per cent of all injury-related deaths and were the leading cause of injury mortality in every group except children younger than one year, for whom homicide was the leading cause. Male death rates were at least four times female rates for suicide, unintentional firearm injury, and injuries related to farm machinery or motorcycles. The drowning rate among Whites was almost twice that of Blacks for ages 1–4, but in the 10–14 year age group the drowning rate for Blacks was over three times that of Whites. In general, the highest injury death rates were in the mountain states and the south. Between 1980 and 1985, the suicide rate in the 10–14 year age group more than doubled. (*Am J Public Health* 1989; 79:310–315.)

Introduction

Injury is the leading cause of death among children above nine months of age in the United States. Injuries cause approximately 44 per cent of all deaths in children ages 1–4, 51 per cent at ages 5–9, and 58 per cent at ages 10–14.[1] The importance of injury deaths in children and young adults is reflected in the fact that injury surpasses all major disease groups as the leading cause of premature years of life lost in this country.[2–5]

We examined 23 categories of fatal childhood injury in the United States, analyzing age, sex, race, and state of residence for the six years 1980–85.

Methods

Mortality tapes for the years 1980 through 1985 were obtained from the National Center for Health Statistics (NCHS). Deaths of children ages 0–14 years, where the underlying event was injury (i.e., coded E800–E999), were analyzed. The 1982 Census Bureau population estimates, multiplied by six, were used as the denominators for calculating the average annual death rates.

Injury deaths were categorized into 23 causes of death based on ICD E-codes. The *expected* number of deaths for each state, based on the death rate for the United States as a whole, was calculated by multiplying the six-year population estimate for the state by the total US death rate for each injury cause. For example, to calculate the expected number of motor vehicle occupant deaths in Alabama, the six-year population estimate of 5,538,000 (the 1982 estimate of 923,000 times six) was multiplied by 3.17/100,000/year (the US motor vehicle occupant death rate) to get 176 expected deaths for 1980 through 1985. As injury death is a relatively rare event in this population, a Poisson distribution was assumed, and 99 per cent confidence limits were calculated for the number of *observed* deaths in each state. In Alabama, the observed number of motor vehicle occupant deaths was 268 with a 99 per cent confidence interval ranging from 226 to 310. If the *expected* number of deaths fell outside the confidence interval set around the *observed* number of death, the state's observed number of deaths was determined to be either significantly high or significantly low. For Alabama, the expected number of motor vehicle occupant deaths, 176, fell well below the lower 99 per cent confidence limit of 226 so Alabama had a significantly high number of observed motor vehicle occupant deaths.

When a state's *observed number of deaths* was significantly high or low, the state was so depicted on a map. In addition, any state whose death *rate* ranked in the top 10 state death rates for a given cause but whose expected deaths fell within the 99 per cent confidence interval of the observed deaths (due to small numbers) were depicted in a separate group called "top ten". All other states were depicted as "average". Sometimes all of the states with the top 10 death rates from a given cause also had significantly high observed numbers of deaths in which case no "top ten" group appears on the map.

Results

National Analysis

During the six-year period 1980–85, almost 10,000 US children ages 0–14 years died of injuries *each year* (Table 1). Thirty-seven per cent of these deaths were related to motor vehicles; this figure includes bicyclist and pedestrian deaths involving motor vehicles. The other leading causes of death were drowning (14 per cent of injury deaths), house fires (12 per cent), and homicide (10 per cent).

When motor vehicle deaths were separated into the subcategories shown in Table 1, the five leading causes of injury death were motor vehicle occupant, drowning, pedestrian, house fire, and homicide. These five causes, in varying order, were consistently the top five in each age, sex, and racial group, with two exceptions: for children less than one year old, suffocation and food aspiration replaced drowning and pedestrian deaths; and for children ages 10–14, bicycles replaced house fires among the top five causes of injury death.

Age: US children ages 0–14 years experienced an average annual death rate of 19.3/100,000 for all injury causes combined during the years 1980–85. The injury death rate was 33.9/100,000/year for children less than one year old, 25.4 for ages 1–4, 14.4 for ages 5–9, and 16.2 for ages 10–14. The relative importance of specific causes of death varied with age (Figure 1). Motor vehicle-related injuries were the largest category for all ages except children less than one year old, for whom homicide accounted for even more deaths than motor vehicles.

The overall death rate from motor vehicles varied less among age groups than most other causes of injury, ranging from 5.5/100,000/year below one year of age to 7.8 for ages 1–

TABLE 1—Injury Deaths by Cause, Ages 0–14, US, 1980–85

Injury Cause	Number of Deaths 1980–85	Average Annual Death Rate per 100,000 Population
Motor vehicle-related, total	22,174	7.2
Motor vehicle occupant	9,796	3.2
Pedestrian, traffic	7,489	2.4
Bicycle	2,194	0.7
Pedestrian, non-traffic	1,276	0.4
Motorcycle	690	0.2
Other motor vehicle-related	729	0.2
Drowning	8,568	2.8
House fire	7,021	2.3
Homicide	5,722	1.9
Suffocation	2,279	0.7
Firearm, unintentional	1,700	0.6
Fall	1,332	0.4
Aspiration, food	1,248	0.4
Suicide	1,214	0.4
Aspiration, other	983	0.3
Poison, solid/liquid	539	0.2
Farm machinery	508	0.2
Electric current	432	0.1
Poison, vapor	384	0.1
Airplane crash	348	0.1
Other unintentional	3,473	1.1
Unknown intent	1,237	0.4
Medical/surgical	539	0.2
All injury (E800–E999)	59,711	19.3

4 years. Differences emerged, however, when motor vehicle deaths were separated into the six subcategories.

Occupant deaths accounted for 90 per cent of motor vehicle-related deaths prior to age 1 and were also the largest subcategory for ages 1–4 (43 per cent) and 10–14 (46 per cent), but pedestrian deaths were paramount at ages 5–9 (47 per cent). Pedestrian non-traffic deaths, which involve a vehicle striking a child in a driveway or on other private property, comprised 17 per cent of motor vehicle-related deaths in children ages 1–4 years. Annually, an average of 212 children died this way, 83 per cent of them 1–4 years of age.

Bicyclist deaths accounted for 12 per cent of the motor vehicle-related deaths in the 5–9 year age group, and 16 per cent for ages 10–14. Sixty per cent of all childhood bicyclist deaths occurred among 10–14 year old children.

Approximately 115 motorcyclist deaths occurred each year, primarily in the 10–14 year age group. Sixty-seven per cent of these children were identified as the driver of the motorcycle. Some deaths in which the vehicle was classified as a motorcycle may have involved miscoded off-road vehicles, such as all-terrain vehicles and minibikes, which should have been included in the category "other motor vehicle."

Sex: The male-to-female ratio of death rates was 1.7 to 1 for all injury causes combined. Male death rates were over four times the female rates for suicide, unintentional firearm injury, and injury related to motorcycles or farm machinery. For males ages 10–14, unintentional firearm deaths were surpassed only by deaths related to motor vehicles and drowning.

Race: Among the four major racial groups, injury death rates were lowest for Orientals and Whites and highest for Native Americans (Table 2). Causes of injury with exceptionally high death rates for Native Americans were pedestrian non-traffic deaths (3.9 times the rate for all children), poisoning by solid or liquid (3.5 times), aspiration of non-food materials (2.6 times), and motor vehicle occupants (2.2 times).

For Oriental children, the death rate from falls was more than twice the rate for all US children. In contrast, the death rate among Oriental children for unintentional firearm deaths was one-eleventh the US rate and their motorcycle death rate was one-seventh the US rate.

Differences between Blacks and Whites in overall death rates decreased with increasing age. The rate for Blacks was 2.5 times the rate among Whites for children less than one

Injury Cause	White	Black	Native American	Oriental	All Races†
All Injuries	17.5 (44,217)	29.3 (13,634)	33.9 (918)	17.5 (917)	19.3 (59,711)
Motor vehicle occupant	3.3 (8,224)	2.6 (1,217)	6.9 (186)	3.1 (162)	3.2 (9,796)
Pedestrian, traffic	2.2 (5,487)	3.8 (1,748)	3.6 (98)	2.9 (153)	2.4 (7,489)
Drowning	2.6 (6,438)	3.9 (1,814)	4.8 (131)	3.4 (180)	2.8 (8,568)
House fire	1.6 (4,080)	6.0 (2,795)	3.3 (90)	1.0 (51)	2.3 (7,021)
Fall	0.4 (933)	0.7 (333)	0.6 (17)	0.9 (49)	0.4 (1,332)
Homicide	1.3 (3,355)	4.7 (2,191)	2.7 (72)	1.9 (101)	1.9 (5,722)

*Rate/100,000/year (total deaths over six-year period in parentheses)
†All Races column includes cases where race was unknown.

year old, 1.8 times for ages 1–4, 1.7 for ages 5–9, and 1.2 for ages 10–14.

House fire and homicide rates for Blacks were more than three times the rates for Whites in all age groups below 10 years. Pedestrian death rates were more than twice as high in Blacks as in Whites for ages 1–4 and 5–9 years. In contrast, the drowning rate among Whites ages 1–4 was almost double that of Blacks. At ages 10–14 years, the most pronounced racial difference was the high death rate from drowning in Blacks (3.4 times the rate for Whites). Black children ages 10–14 continued to experience high homicide and house fire death rates compared to Whites, while White children in this age group had substantially higher death rates than Blacks for motor vehicle occupants, suicide, unintentional firearm deaths, motorcycles, and suffocation.

Time Trends: The injury death rate for the US population ages 0–14 decreased by 16 per cent between 1980 and 1985, from 21.6 to 18.2/100,000/year (Table 3). The greatest decreases occurred in the youngest children: 25 per cent for children less than 1 year old, 21 per cent for ages 1–4, and 19 per cent for ages 5–9, compared to 7 per cent for ages 10–14.

Death rates declined for almost all causes of injury during this time period (Table 3). Among the leading causes of fatal injury, the greatest decreases were seen in rates of drowning and pedestrian deaths. The motor vehicle occupant death rate declined by 14 per cent for all ages combined, with dramatic differences among age groups. Children under 1 year experienced a 32 per cent decrease, ages 1–4 years a 22 per cent decrease, ages 5–9 years an 11 per cent decrease, and ages 10–14 only a 3 per cent decrease. The suicide rate for ages 10–14 more than doubled.

Geographic Variations

Analysis at the state level found more than a three-fold difference among the states with the highest and lowest injury death rates. Injury death rates for all children ages 0–14 ranged from 11.2/100,000/year in Massachusetts to 35.0/100,000/year in Alaska. In general, the highest rates were in the mountain states and in the south, and the lowest rates were in New England, the mid-Atlantic states, and the midwest.

In every state, total motor vehicle deaths surpassed deaths from any other injury cause. Furthermore, in 26 states, the subcategory of motor vehicle occupants outranked deaths from any other category (Appendix). Deaths due to house fires outnumbered those from any other specific injury cause in 11 states, while drowning was the leading injury cause of death in 10 states. Pedestrian deaths ranked first in three states, as did homicide in Washington, DC.

Motor vehicle occupant deaths (Figure 2) were high in the south and southwest. The highest rates were in Idaho (7.4/100,000/year), New Mexico (6.6), and Wyoming (6.5), which

TABLE 3—Death Rates,* Number of Deaths and Per Cent Change in Death Rates, 1980–85, by Cause of Injury, Ages 0–14, US

Injury Cause	1980	1985	Percent Change in Rates
All Injury	21.61 (11,084)	18.19 (9,449)	−16
Suicide (ages 10–14)	0.76 (139)	1.61 (275)	+112
Homicide	1.84 (944)	1.86 (967)	+1
Poison-gas, vapor	0.10 (52)	0.10 (54)	0

Aspiration-food	0.53 (274)	0.35 (180)	−34

*Rate/100,000/year
Number of Deaths in parentheses.

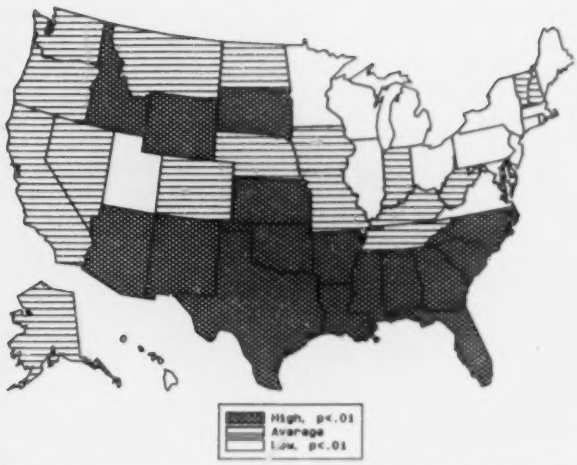

FIGURE 2—Motor Vehicle Occupant Deaths by State, Ages 0–14 Years, US 1980–85

contrasted sharply with the relatively low rate in nearby Utah (2.4).

House fire deaths (Figure 3) showed a distinct geographic pattern, with high rates in the east, especially the southeast, and low rates in the west.

Drowning rates (Figure 4) ranged from 0.8/100,000/year in Rhode Island to 6.8 in Alaska. California, Oregon, and Utah are among the states with significantly high numbers of drowning deaths, although they do not have significantly high numbers of deaths for most other causes.

Death rates from unintentional firearm injury ranged from zero in Rhode Island to 2.1/100,000/year in Alaska. The rates were highest in the south and in the northern mountain states (Figure 5).

Farm machinery death rates were highest in northern farm states: Idaho, South Dakota, Wisconsin, Vermont, Iowa, and Minnesota had rates ranging from 0.6 to 0.9/100,000/year. Deaths from farm machinery had the highest rates among 1–4 year olds and occurred predominantly (80 per cent) among White males. In Wisconsin children ages 1–4, farm machinery deaths were surpassed only by deaths due to motor vehicles, house fires, and drowning (data not shown).

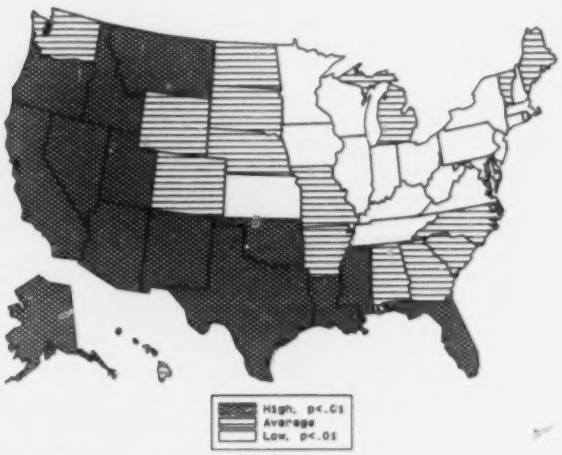

FIGURE 4—Drowning Deaths by State, Ages 0–14 Years, US 1980–85

Homicide rates ranged from 0.7/100,000/year in New Hampshire to 3.0 in Delaware and 4.6 in Washington, DC. High homicide rates were seen throughout the southwest as well as in states with large urban populations (Figure 6).

Suicide rates (Figure 7) are mapped for the 10–14 year age group because only 2 per cent of the childhood suicides occurred in younger children. Suicide rates were generally highest in the northern and mountain states; they ranged from a low of 0.3/100,000/year in North Dakota to 2.1 or higher in Wyoming (3.3), New Mexico (2.7), Idaho (2.4), and Colorado (2.1).

Discussion

Childhood injury death rates have been decreasing for decades[3,6] and it is encouraging that both the frequency and the rate of death from all injuries combined have continued

FIGURE 3—House Fire Deaths by State, Ages 0–14 Years, US 1980–85

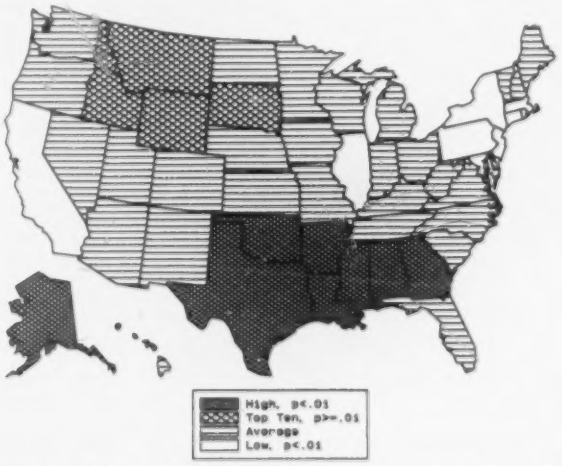

FIGURE 5—Unintentional Firearm Deaths by State, Ages 0–14 Years, US 1980–85

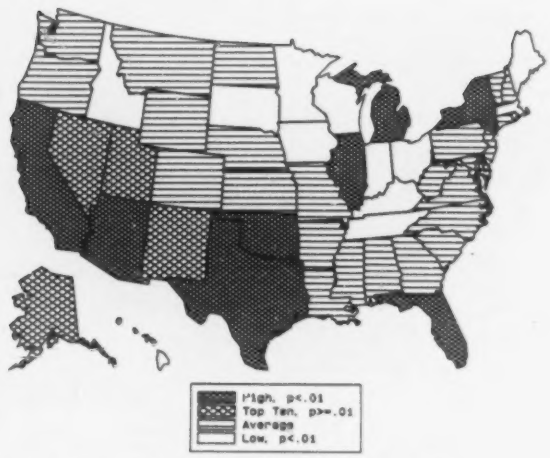

FIGURE 6—Homicides by State, Ages 0–14 Years, US 1980–85

to decrease in recent years. Major causes of unintentional injury death continue to be motor vehicle occupants, pedestrians, drowning, and house fires. The importance of homicide during the first year of life—often representing lethal cases of child abuse—and the increasing rates of juvenile suicide are matters of special concern because they reflect personal, family, and social disruption.

Identifying states with the highest rates of a specific injury cause of death may suggest a likely causal factor. For example, the high house fire death rates in the south and east suggest that the older and/or wooden houses, more commonly found in these regions[3,7] may be a contributing factor. In addition, the National Fire Data Center suggests that low income and education levels and large numbers of families living in poverty, particularly prevalent in the southeast, may contribute to high fire death rates.[8] Similarly, an especially low death rate may be revealing. For example, the low rate of motor vehicle occupant deaths in Utah suggests a beneficial effect on children of social policies (reflecting, in this instance, religious tenets) that reduce alcohol use by adults. The motor vehicle occupant death rate per billion vehicle miles is also low in Utah[3] as well as the per capita consumption of alcohol, which is the lowest in the country.[9]

It is also important to look at the rankings of causes *within* a state. In Maine and Virginia, the house fire death rate is not substantially higher than in the US as a whole—yet house fires are a major problem in these states, with death rates even higher than the rates for motor vehicle occupants. This type of information can be helpful to a state interested in targeting its own most serious problems.*

Limitations of this study include possible coding variations among states. It is unlikely that different coding practices affected the major causes of injury death, since motor vehicle-related injury, drowning, house fire, and homicide are clearly defined and recognizable throughout the country. However, coding of some less prominent injury causes may vary. For example, mechanical suffocation and aspiration, to which about one-third of all injury deaths in children under one year of age are attributed, may be confused with each other and may include miscoded cases of Sudden Infant Death Syndrome (SIDS). More accurate coding of SIDS in recent years may, in part, account for the decrease in deaths coded to aspiration in children less than one year old.

The use of data from a six-year period made it possible to examine causes of death and population subgroups that are rarely considered. For example, pedestrian deaths in non-traffic locations such as driveways and parking lots comprise only 2 per cent of all injury deaths, but 17 per cent of all motor vehicle-related deaths in 1–4 year olds. An examination of pedestrian deaths for this age group in Washington State indicates that fatalities occurring in non-traffic situations may often be misclassified as traffic-related.[10] From 1979 to 1983, one-third of the pedestrian traffic deaths to children under five years of age in Washington State were re-classified as non-traffic deaths when additional information from different data sources was considered. Thus, non-traffic pedestrian deaths may be an even more important cause of death for young children than national data indicate.

The differences observed among racial groups indicate the need for prevention efforts focused on the particular injury problems of certain subpopulations. Falls cause 5 per cent of injury deaths in Oriental children, compared to only 2 per cent in all other children. Falls from or out of buildings are overrepresented among fall deaths in Oriental children when compared to fall deaths in children of other races, suggesting that an urban living environment may contribute to high fall death rates in Oriental children.[11] Data from Korea, where injury mortality patterns are generally quite similar to the US but where the death rate from falls in children ages 1–4 years is over seven times the US rate, suggest a possible cultural difference in the perception of falls as a threat to children's lives.[12]

The high injury death rates in Native American children, as well as the predominance of males among all causes of injury death, were also found in a recent study of childhood injury mortality in Canada.[13] The finding that race differentials in total injury mortality rates decrease with increasing age is consistent with previous research, as is the observation that large race differences still exist for specific injury causes within age groups.[14] For example, the drowning rate for ages 1–4 is highest in White children, probably because of their greater exposure to swimming pools, but for ages 10–14 is far higher for Blacks. Socioeconomic differences have repeat-

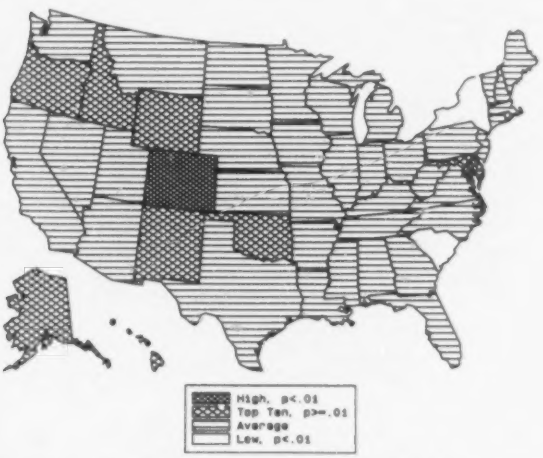

FIGURE 7—Suicides by State, Ages 0–14 Years, US 1980–85

*Detailed data for each state are available from the authors.

edly been shown to be related to differences in injury occurrence as well as injury prevention understanding and behaviors.[15–17] The racial differences revealed by this study most likely reflect differences in income, education, and other aspects of socioeconomic status among racial groups in the US.

This study indicates that in certain geographic areas or for specific population subgroups it is possible to identify injury problems that are often masked in larger, less specific categories. Such identification increases the likelihood that specific injury problems will be targeted and given higher priority in prevention programs, eventually leading to a reduction in injury mortality.

Incidence, Causes and Severity of Injuries in Aquitaine, France: A Community-Based Study of Hospital Admissions and Deaths

L. Tiret, PhD, B. Garros, MS, P. Maurette, MD, V. Nicaud, MS, M. Thicoipe, MD, F. Hatton, MD, and P. Erny, MD

Abstract: This paper reports the results of a study of injuries conducted during a one-year period within a defined geographic population of 2.7 million persons (Aquitaine, France). Cases were defined as unintentional or intentional injuries, either resulting in immediate death before reaching hospital or requiring hospital admission. During the one-year period, 1,181 deaths were registered and 8,190 hospital admissions occurred during the sample periods. The three leading causes of injury were falls (40 per cent), traffic accidents (27 per cent), and poisonings (15 per cent). The overall incidence of injuries was 136 per 10,000 person years. Incidence by sex and age was assessed for the main external causes. The ratios of nonfatal to fatal cases were calculated by sex and age and by external cause. The origin of the injury was suicide in 14 per cent of cases and assault or homicide in 3 per cent. The severity of injuries, assessed using an automatic computation of the Injury Severity Score (ISS), ranged from 1 to 66 with a mean of 6.9. Substantial variations of ISS were observed according to external cause. At the 8th day following admission, 31 per cent of hospital-treated patients were still hospitalized and 0.8 per cent had died in hospital. The outcome correlated well with the ISS. (*Am J Public Health* 1989; 79:316–321.)

Introduction

Injuries constitute a major health problem in all developed countries and in an increasing number of developing countries. They have been examined by mortality data[1,2] or by morbidity data focusing either on the pediatric population[3–7] or on specific injury types, such as head traumas,[8,9] burns,[6,10] or motor vehicle injuries.[7,11] Very few studies describe the nature of the problem as a whole within an entire population. In some countries, routine statistics[12,13] or permanent surveys, such as the National Health Interview Survey in United States,[14] provide annual estimates of the incidence of injuries but without great detail. More information was gathered by the Northeastern Ohio Trauma Study,[15,16] carried out in 1977 in the United States. However, that study did not include fatal cases and did not provide an evaluation of the severity of injuries.

This paper reports the first results of an epidemiological study of injuries conducted during 1986 among a defined geographic population in France. Its aims were to provide estimates of the incidence of fatal and nonfatal cases of injury, to describe their external causes, and to assess the severity of injuries using the Injury Severity Score (ISS) derived from the Abbreviated Injury Scale (AIS),[17] the most widely used score for rating severity of multiple injuries.[18–21]

Methods

The study was carried out prospectively over a one-year period in the Aquitaine, one of the 22 administrative regions of France. This region contains both urban and rural areas; its main city is Bordeaux. It is bordered by the western Atlantic coastline and the southern mountain range of Pyrénées. Extrapolating from the 1982 census, the 1986 population was estimated to be 2.7 million persons (4.9 per cent of the whole population of France), of which 16 per cent were over 65 years of age. The study was based on an administrative region since in the French health care system, each region constitutes an independent entity and people normally receive medical care in their region of residence. The presence of a referral teaching hospital in the region reduces the possibility of transfer for specialized treatment outside the region.

Case Definition

Cases were defined as those injuries sustained in Aquitaine between December 1985 and December 1986, either resulting in immediate death before reaching hospital, or requiring hospital admission in a private or public institution of the region. Injuries to residents and non-residents of the region were both recorded but the latter were excluded from the data reported here. The field of study included both unintentional and intentional injury cases (the latter including homicides, assaults, suicides, and self-destructive actions). Surgical and medical misadventures (corresponding to codes E870–E879 and E930–E949 of the International Classification of Diseases—9th revision[22]) and late effects of accidental injury (E929) were excluded.

Data Collection

All public and private hospitals regularly involved in the treatment of injuries, because of their geographical position or the presence of a trauma specialist, were included in the study. Among other hospitals, one out of two was randomly selected. In each institution, the survey lasted 13 weeks spread over the whole year:

- the teaching hospital was investigated every fourth week;
- non-teaching and private hospitals of the first category were divided into four groups, each being investigated during three periods (4 weeks, 4 weeks, and 5 weeks). The survey was initiated successively in each group with an interval of four weeks, the whole year therefore being covered by the study;
- private hospitals of the second (non-trauma) category were divided into two groups, each being successively investigated during a 13-week period.

This scheme provided a sample representative by time of day, day of the week, and season.

Injury cases resulting in death before reaching hospital were recorded from death certificates. All cases registered in the region during the one-year period were included, except for those having been registered in a hospital or a clinic.

Data Collected

For each injury case requiring hospital admission, the medical staff of the institution completed a questionnaire within the first 24 hours following admission. Data collected concerned the demographic characteristics, time and place of injury, origin, cause and clinical nature of injury. Causes of injury and poisoning were coded into 14 specific categories. Cases with two or more possible causes were coded according to the primary harmful event. Outcome within eight days of injury was added later. The clinical nature of traumatic injuries was coded according to a classification specially devised for this study by a multidisciplinary workgroup, including trauma specialists and epidemiologists. The purpose of this classification was to provide an automatic computation of the ISS. The descriptive lesions, taken directly from the AIS-80 manual,[17] were condensed into 200 codes being organized within the six body regions defined for the ISS. A defined injury code corresponded either to one specific lesion or to a group of several lesions of a same anatomic site and having an identical AIS severity level. The person in charge of completing the questionnaire simply had to circle the codes relative to all injuries sustained, then an AIS grade was automatically assigned to each injury code by a computer algorithm and the ISS was computed.*

A test to control the adequacy of ratings by this method was undertaken on 164 patients treated in an emergency department. One physician computed the ISS using the manual. The same lesions were then coded in the questionnaire and the ISS was derived by the algorithm. In 14 per cent of cases, there were slight discrepancies between the two ratings, due to the adaptation, which over-simplified some categories of lesions in the AIS, such as spinal lesions.

The completeness of the notification of cases was checked by two supervisors for each period of survey, from the list of admissions to the institutions.

Analysis

Patients of unknown age and sex were excluded from the analysis (1 per cent of total). In the event of transfer, only the first hospital admission for the episode was considered. Data concerning hospital admissions were extrapolated from the sample to provide annual estimates. To improve the accuracy of estimated injury rates, an attempt was made to adjust for the missing cases diagnosed outside the region. This adjustment was made on the basis of the 1984 mortality statistics.[23] Among deaths from injury having occurred in residents of Aquitaine, the proportions of cases registered outside the region were calculated by sex and age group, and the estimated injury rates were increased by the same proportions, on the assumption that admissions and deaths follow the same pattern. This proportion varied from 3.9 per cent to 10.7 per cent (6.3 per cent for the entire population).

Tables concerning the ISS were derived only from the admission sample, since this information was not available for death cases. ISS was analyzed both as a continuous variable and in classes, those being the categories widely used.[19,24]

*Details about the methodology are available from the author on request.

Results

All 21 public hospitals and 38 of the 43 private hospitals participated in the study. The participating institutions accounted for 97 per cent of the total traumatological activity in the region. The coefficient of extrapolation from the sample of admissions was 4.09.

Incidence

During the one-year period, 1,181 deaths were registered from the death certificates and 8,190 hospital admissions were observed during the sampling periods among residents of Aquitaine. After extrapolation of admissions on an annual basis and adjustment for the potential cases diagnosed outside the region, the overall incidence was 135.9 per 10,000 person years.

As expected, injury rates varied considerably by sex and age (Table 1). Men between 15 and 24 years of age and women over 75 years of age experienced the highest overall injury rates; except for ages 65 and over, male rates exceeded female rates, the difference being especially marked in the 15–34 year age group. However, mortality rates for males markedly exceeded those for females at all ages except those under age 10. In both sexes, mortality rates were highest over 75 years of age.

There was one immediate death for every 30 hospital admissions. The rate ratio of nonfatal to fatal cases was very high during childhood, then decreased until age 65 for females and age 75 for males. Except under age 10, the ratio was lower in males than in females.

External Cause of Injury

For all ages combined, falls on same level were the most common cause of fatal and nonfatal injuries (Table 2). When adding falls from high level, falls represented nearly 40 per cent of all reported cases of injury, yielding an incidence of 52 per 10,000 person years. Traffic accidents were the second commonest cause, followed by poisonings. These three leading causes accounted for 80 per cent of all admissions and deaths. When considering only fatal cases, the rank ordering of causes differed markedly. Traffic accidents ranked first, followed by accidents caused by firearms, hanging and strangulation, and drowning. The cause of injury was unspecified in 8 per cent of death certificates.

The nonfatal to fatal case rate ratio varied considerably with external cause of injury. For example, there was one immediate death in 150 admissions from falls on same level, against one in 20 from traffic accidents. In cases of drowning and hanging, the number of immediate deaths exceeded that of admissions. The ratio was also very low for injuries caused by firearms or electricity and very high for injuries produced by blunt objects and cutting or piercing instruments.

Origin of Injury

Among fatal and nonfatal cases of injury, 13.9 per cent were suicides or attempted suicides and 2.7 per cent were assaults or homicides (Table 3). Suicides and attempted suicides accounted for more than 80 per cent of cases of hanging/strangulation and poisonings, more than half of injuries due to firearms, and one-third of drownings. It should be noted that for this last cause, the origin was unknown in nearly 10 per cent of cases. More than 25 per cent of injuries from firearms were of accidental origin, hunting being a common sport in Aquitaine. Two suicides by electricity were reported.

	Both	8,190	131.3	1,181	4.6	135.9	28.4

*Rates were adjusted for the potential cases diagnosed outside the region.

Cause of Injury by Sex and Age

For both sexes, falls and traffic accidents ranked among the three leading causes at any age. Women over 75 years of age experienced the highest rate of falls on same level. Men were more exposed than women to falls from a high level, except during childhood where rates were similar in both sexes. Traffic accidents showed a marked peak in the 15–24 year age group, with a male/female ratio of incidence in this group of 2.5. Two distinct poisoning risk groups emerged: the first under 5 years of age, corresponding to accidental cases, and the second between 15 and 44 years of age, more marked in females and corresponding primarily to intentional poisonings. Injuries produced by blunt objects and cutting/piercing instruments showed an excess of male cases mainly concentrated during the working ages. Burns were more frequent in males at any age, and in both sexes, the highest risk was experienced under 5 years of age (Table 4).

Injury Severity Score (ISS)

Among patients having sustained traumatic injuries, the ISS ranged from 1 to 66 with a mean of 6.9. Eleven per cent of patients had an ISS higher than 10. Accidents caused by firearms yielded the highest values of both mean and proportion of ISS above 20. Traffic accidents and burns were also associated with a mean ISS value above average. Falls on same level often led to a score of 9, reflecting the fractures of limbs. In contrast, falls from high level were associated with higher proportions of scores in extreme classes, reflecting

*Admissions × 4.09 + deaths.

accidents of different severity. Being struck by an object or cutting/piercing from instruments produced the least severe injuries (Table 5).

Outcome of Patients Admitted to Hospital

On the eighth day following injury, 31 per cent of patients admitted to hospital were still hospitalized and less than 1 per cent had died in hospital. When controlled for age by using the Standard Morbidity Ratio (SMR), burns, firearm accidents, and traffic accidents had proportions of patients still hospitalized above average. Hospital mortality was higher than average for traffic accidents, firearms and hanging, and lower for poisonings (Table 6).

The outcome within eight days correlated well with the ISS, mortality after admission and length of hospitalization both increasing with the score (Table 7).

Discussion

In contrast to studies based on medical records,[3,4,15] our data were specifically collected for this study, using an ad hoc questionnaire. This system of data collection was time-consuming for the medical staff of institutions in charge of completing questionnaires but, in return, data were more comprehensive and relevant than those derived from routine medical records.

This study does contain a number of possible biases. First, the field of study was limited to severe cases, i.e., cases either resulting in immediate death or requiring hospital admission. Hospital admission may be influenced by several factors independent of the actual severity of injury such as age, social conditions, access to medical service, hospital admission policy. Nevertheless, this criterion was no more subjective than the fact of attending at an accident and emergency department.

Concerning the sample of admissions, five of 43 private hospitals did not participate in the study. The extrapolation from the sample was adjusted for these missing data, taking surgical activity as criterion of reference although this did not exactly reflect the traumatological activity.

In participating institutions, completeness of notifications was checked by two supervisors using the list of admissions, but this list was not available in all private hospitals and some underreporting of cases in these institutions cannot be excluded. However, private institutions accounted for only 25 per cent of all admitted cases.

The number of deaths before admission may also be underestimated, since in case of a "suspect" cause of death, some certificates may have been sent directly to the legal authorities. These cases are later re-included in official mortality statistics, but they often have an unspecified cause of death, since legal authorities do not always send back the relevant information. In the 15–34 year age group, where it can be assumed that unspecified causes correspond mainly to violent deaths, we can predict from official mortality statistics that we may have missed about 9 per cent of cases. This

All traumatic causes	43.7	44.9	8.4	3.0	6.9 (0.07)	1–66

underestimation presumably affected suicides and homicides.

With respect to the estimates of injury rates, we had to assume that fatal and nonfatal cases followed the same pattern for potential cases diagnosed outside the region, an assumption which may not be accurate.

Lastly, hospital mortality possibly is underestimated, since in cases of a secondary transfer to another institution, the occurrence of death in the secondary institution was not known. However, this underestimation is doubtless slight (only 4 per cent of cases were secondarily transferred). Hospital mortality assessment was limited to eight days, because it did not seem feasible to maintain a longer follow-up in all institutions. This limitation does not affect equally all types of injury, delayed deaths being more frequent for some causes and ages.

The comparison of our results with those of other studies is difficult since many differences exist in definition and case ascertainment, time and place of study, and analysis. Nevertheless, many findings are similar to those reported by previous studies,[3,4,12–16] concerning the main causes of injury and the patterns of incidence by age and sex.

The major contributions of this study lie in two areas. First is the assessment of the ratio of nonfatal to fatal cases.

TABLE 6—Outcome at the Eighth Day following Injury of Patients Admitted to Hospital, according to External Cause of Injury

SMR = Standardized morbidity (mortality) ratio. SMR = [Observed number of cases still hospitalized (died) for a given cause/Expected number when applying the overall rate of patients still hospitalized (died)]. *$p < 0.001$; °$p < 0.05$; +expected number smaller than 5.

TABLE 7—Outcome at the Eighth Day following Injury of Patients Admitted to Hospital, according to Classes of ISS

Classes of ISS	% Still Hospitalized	% Died in Hospital
1–4	17.7	0.1
5–9	42.2	0.5
10–19	58.5	1.1
≥20	69.9	18.5

The ratio is very high during childhood, because hospital admissions are frequent and mortality very low. From 15 to 75 years of age, the ratio regularly decreases since rate of fatal cases increases, while that of nonfatal cases decreases. In the elderly, the ratio rises again, especially in women, despite a continuing increase of immediate mortality. This is explained by the high admission rates at this age and by the fact that deaths are more often delayed, as mentioned above. The low ratios of nonfatal to fatal cases for certain external causes, such as accident by firearms, drowning, and hanging/strangulation, emphasize the fact that studying severe cases only from hospital-treated cases does not provide an accurate view of the magnitude of the problem.

The second contribution of this study is an in-depth description of the severity of injuries using the ISS. We have not found such an evaluation of the ISS within an entire injured population in the literature. The ISS was initially developed for traumas resulting from traffic accidents, but according to its authors, its use for rating other accidents is possible on condition that similar injuries are involved.[18] Moreover, the 1980-AIS version incorporated many more injuries to internal organs, making the AIS more suitable for rating severity of non-vehicular penetrating injuries.[21] Its application may be questionable for rare causes, such as firearm accidents.[25]

We developed a methodology for automatically computing the ISS, as proposed by other authors.[26] The purpose was to eliminate the inter- and intra-rater variability among coders, a problem which has been often pointed out.[21,25–27] This problem was important in our study, which involved many institutions. Automatic computation was also time-saving and less costly, two necessary conditions to make the study feasible, even at the expense of some loss of precision. MacKenzie,** reporting the results of an experiment of conversion of the International Classification of Diseases to AIS, had already stimulated interest in such a tool, even not perfect.

The ISS could be assessed only on patients admitted to hospital, since in cases of death a postmortem examination would have been necessary to identify all lesions. This minimizes the proportion of upper scores for causes having a high immediate mortality, such as traffic accidents or firearms injuries. Despite this bias, these causes were nevertheless associated with the highest severity scores among hospital-treated patients.

This study confirmed that the ISS correlated well with mortality and length of hospitalization, as previous studies have reported.[18,19] However, it is not a good predictor of

**McKenzie EJ, Steinwachs DM, Shankar B: Classifying trauma severity based on hospital discharge diagnoses: validation of an ICD-9CM to AIS-85 conversion table (not published).

post-trauma disability.[24] Further exploration of this last aspect is needed as the improvements in survival from injuries may lead to an increase in later disability.

ACKNOWLEDGMENTS

This study was supported by the Direction Régionale des Affaires Sanitaires et Sociales d'Aquitaine, the Conseil Régional d'Aquitaine, the Caisse Régionale d'Assurance Maladie d'Aquitaine, the Ministère de l'Equipement, du Logement de l'Aménagement du Territoire et des Transports (Sécurité Routière), and the Ministère de l'Intérieur (Sécurité Civile). The authors gratefully acknowledge the cooperation given by the institutions which participated in the study. We also wish to thank E. Michel and V. Lambert for computer programming, C. Cretaz for collecting deaths certificates, and B. Mrabet and D. Rebeyrol for supervising the data collection in institutions.

APHA Issues New AIDS Report:
Contact Tracing and Partner Notification

The American Public Health Association's Special Initiative on Acquired Immune Deficiency Syndrome (AIDS) recently released its second report, entitled *Contact Tracing and Partner Notification*. This new report, which was prepared by the Association's AIDS Working Group, presents the historical and scientific basis for contact tracing and partner notification in the control of sexually transmitted diseases. The report also discusses those factors which should be considered before deciding if contact tracing is a desirable public health strategy in preventing the transmission of the human immunodeficiency virus (HIV) which causes AIDS.

Single copies of *Contact Tracing and Partner Notification* are available for $3 prepaid from APHA Publication Sales, 1015 15th Street, NW, Washington, DC 20005. Bulk rates are also available on request. Telephone (Publication Sales): (202) 789-5666.

The first report prepared by the APHA AIDS Working Group, released last year, was entitled *Casual Contact and the Risk of HIV Infection*. That 12-page report presents the epidemiologic and scientific evidence regarding the major routes of HIV, the rare routes of HIV infection, and those routes that do not transmit HIV. Single copies of *Casual Contact and the Risk of HIV Infection* are available for $3 prepaid from APHA Publication Sales (address and phone number above). Bulk rates also available.

Sport Fish Consumption Advisories and Projected Cancer Risks in the Great Lakes Basin

JEFFERY A. FORAN, PHD, MICHAEL COX, MPH, AND DAVID CROXTON, MPH

Abstract: Because Great Lakes sport fish are contaminated with several toxicants, the Great Lakes states individually issue advisories, principally based on Food and Drug Administration (FDA) action levels, that suggest limiting or eliminating consumption of contaminated fish. We describe the procedures the states use to determine when to issue consumption advisories and we evaluate the associated cancer risks using EPA-IARC-OSTP risk assessment procedures. Projected cancer risks are high for consumers of small quantities of sport fish contaminated with DDT or dieldrin at their respective action levels. Projected risks at concentrations that are common but below the action levels are also substantial. We propose that sport fish with tissue concentrations of DDT or dieldrin one-fifth and one-third of the action levels should be covered by consumption advisories to warn consumers of the potential adverse health impacts. (*Am J Public Health* 1989; 79:322–325.)

Introduction

Contamination of the sport fishery in the Great Lakes basin (Lakes Michigan, Huron, Superior, Erie and Ontario and their connecting waters) has been a highly sensitive environmental and human health problem. Since the early 1970s, states in the Great Lakes basin (Illinois, Indiana, Michigan, Minnesota, New York, Ohio, Pennsylvania, Wisconsin) individually have issued annual consumption advisories that suggest reduction or elimination of the consumption of contaminated sport fish. Following the Great Lakes Toxic Substances Control Agreement, states were partially successful in implementing coordinated advisories in 1986. These advisories are based on Food and Drug Administration (FDA) action levels for commercial fish and vary substantially among the states. Whether the consumption advisories protect the population is not known.

In this report, we describe the different consumption advisories, which are dependent upon tissue concentrations of contaminants in local fish populations and we use quantitative cancer risk assessment to evaluate their efficacy.

Methods

We calculated risk projections for two contaminants of Great Lakes sport fish, DDT (1,1,1,-trichloro-2,2-bis[p-chlorophenyl]ethane) and dieldrin (1,2,3,4,10,10-hexachloro-6,7-epoxy-1,4,4a,5,6,7,8,8a-octahydro-endo-exo-1,4,:5,8-dimethanonaphthalene), partly because of recent regulatory action on these materials.[1,2]

Projected risks were calculated following the guidelines of the US Environmental Protection Agency (EPA),[3,4] Office of Science and Technology Policy (OSTP),[5] and the International Agency for Research on Cancer (IARC).[6] We used data from the studies of mammalian toxicity for DDT and dieldrin conducted by Cabral, *et al*,[7] Tomatis, *et al*,[8] and Walker, *et al*.[9] We used the multistage model[10] (Global 82) for extrapolation from high to low doses and rodent to human scaling factors. For each combination of fish consumption and contamination level, we computed four cancer risk estimates by using either rat or mouse experimental data and either surface area or body weight scaling to estimate 95 per cent upper bound risk projections.

Concentrations of DDT (expressed as total DDT) and dieldrin in the edible tissue of Great Lakes sport fish (coho, chinook and king salmon, and lake trout) varied widely throughout the Great Lakes during 1986 (0.01 mg/kg (ppm) to 1.5 mg/kg for total DDT and 0.01 mg/kg to 0.2 mg/kg for dieldrin, Michigan Department of Natural Resources and Wisconsin Department of Natural Resources, unpublished data). Both DDT and its metabolite DDE are found in Great Lakes sport fish, with long range atmospheric transport acting as a continuing source of DDT to the Great Lakes. We chose intermediate tissue concentrations of DDT (total) and dieldrin (1.0 mg/kg and 0.1 mg/kg) to represent those found in many Great Lakes sport fish in 1986 and to be used for comparisons with FDA action levels. The FDA action level for DDT in fish is 5.0 mg/kg (ppm) and 0.3 mg/kg for dieldrin.

Three levels of consumption used in the risk assessment range from the US national average (6.5 g/day or less than one portion per month weighing one half pound)[11] to 96 g/day (approximately three, half pound portions per week) over a lifetime. Surveys suggest that the average consumption rate of sport fish by anglers and their families in the Great Lakes basin ranges from 10 to 50 g/day[12–14] but that some individuals may consume sport fish at least three times per week (96 g/day).[15]

Results

States surrounding Lake Michigan issue consumption advice for sport fish based on the number of fish sampled with edible tissue concentrations that exceeded the FDA action level for individual contaminants (Table 1). States surrounding the other Great Lakes generally issue advice based on the mean tissue concentration for individual contaminants. Consumption advice is modified by the states annually and is issued on a location, species and size-class specific basis.

Cancer risk projections (Table 2) range as high as 1.05×10^{-2} (one excess occurrence of cancer during the lifetimes of 100 exposed individuals living to age 70) for dieldrin and as high as 2.8×10^{-3} for DDT when consumption is 96 g/day (three portions per week) and fish are contaminated with DDT and dieldrin at their respective action levels (5.0 mg/kg, 0.3 mg/kg).

When 10 per cent to 50 per cent of sampled Lake Michigan sport fish are contaminated with DDT or dieldrin at or above action levels, consumers are advised to reduce consumption of

TABLE 1—Process for Developing Sport Fish Consumption Advisories for the Great Lakes (excludes Ontario)

Lake	Advice		
	Unrestricted Consumption (Category 3)	Restrict Consumption* (Category 2)	Do Not Eat (Category 1)
Michigan	0–10% of fish sampled exceed Action Level	11–50% of fish sampled exceed Action Level	>50% of fish sampled exceed Action Level
Huron	Mean Tissue Concentration < Action Level	Mean Tissue Concentration > Action Level	Mean Tissue Concentration > 2X Action Level
Erie	Mean Tissue Concentration < Action Level	Advice Not Given	Mean Tissue Concentration > Action Level
Superior	variable**	variable**	Mean Tissue Concentration > Action Level
Ontario	None	All fish[a] Mean Tissue Concentration 1.5–3 X AL[b]	Mean Tissue Concentration > 3X AL[b]

Note: All advice is based on the concentration of contaminants in edible tissue of individual sport fish species or size classes of individual species.

*States advise that women of child bearing age, pregnant women, and children do not eat any fish in this category.

**Advice for these categories is based on FDA Action Levels but the procedure for applying action levels is highly variable within and between states.

[a]New York issues general advice that all fish should not be consumed more than once per week.

[b]This advice is based on an additivity formula where concentrations of more than one contaminant in fish tissue are combined. Where this combination of contaminants is 1.5–3X the combined action level, New York advises that these fish should not be eaten more than once per month.

these species and size classes of fish to not more than one portion per week. When more than 50 per cent of sampled fish contain contaminants above the action level, no consumption is recommended. Cancer risk projections associated with consumption of one portion per week (32 g/day) of fish with tissue concentrations at action levels range as high as 9.4×10^{-4} for DDT and as high as 3.8×10^{-3} for dieldrin (Table 2).

Although concentrations of DDT and dieldrin in the edible tissue of Great Lakes sport fish were below action levels in 1986, cancer risk projections associated with tissue concentrations of 1.0 ppm DDT or 0.1 ppm dieldrin range as high as 5.7×10^{-4} for DDT and 3.7×10^{-3} for dieldrin. At a fish consumption rate of 32 g/day, risk projections associated with these tissue concentrations range as high as 2.0×10^{-4} for DDT and 1.5×10^{-3} for dieldrin.

All of the projections cited above were derived using a

TABLE 2—95 Per Cent Upper Bound Cancer Risk Projections in Humans Exposed to Fish Contaminated with DDT or Dieldrin

Fish Consumption (g/d)*	SCL[a]	ANM[b]	Tissue Concentration (PPM)

		R	1.7×10^{-6}	7.0×10^{-6}		
	SA	M	4.8×10^{-5}	2.0×10^{-4}	5.86×10^{-4}	1.04×10^{-3}
		R	9.5×10^{-8}	3.9×10^{-5}		
32.0	BW	M	1.5×10^{-5}	7.1×10^{-5}	1.13×10^{-4}	2.93×10^{-4}
		R	7.2×10^{-6}	3.3×10^{-5}		
	SA	M	2.0×10^{-4}	9.4×10^{-4}	1.49×10^{-3}	3.76×10^{-3}
		R	4.0×10^{-5}	1.9×10^{-4}		
96.0	BW	M	4.3×10^{-5}	2.1×10^{-4}	2.93×10^{-4}	7.89×10^{-4}
		R	2.0×10^{-5}	9.9×10^{-5}		
	SA	M	5.7×10^{-4}	2.8×10^{-3}	3.65×10^{-3}	1.05×10^{-2}
		R	1.1×10^{-4}	5.5×10^{-4}		

*32 g/day = 1/2 pound/week

†FDA action level.

[a]SCL - BW = body weight scaling factor, SA = surface area scaling factor

[b] ANM - M = mouse, R = rat

rodent to human scaling factor based on surface area. A body weight scaling factor reduces risk projections, generally by an order of magnitude for any consumption level and tissue concentration. Use of a body weight scaling factor results in risk projections greater than 1×10^{-5} for all consumption rates of dieldrin and greater than 1×10^{-6} for DDT (Table 2). Use of a body weight scaling factor results in risk projections as high as 7.9×10^{-4} for dieldrin and 2.1×10^{-4} for DDT when fish contaminated at the action level are consumed three times per week. Risks associated with consumption of fish contaminated at current levels range as high as 2.9×10^{-4} for dieldrin and 4.3×10^{-5} for DDT at a consumption rate of 96 g/day. Thus, while the use of a body weight scaling factor results in lower cancer risk projections, these projections are still high for all but the lowest consumption rates and tissue concentrations.

Finally, the use of toxicological data derived from a rat study for DDT results in differences in risk projections of less than an order of magnitude compared with risk projections derived from toxicological data from the mouse study. This is true for comparisons within any consumption level and tissue concentration.

Discussion

Our projections suggest that current consumption advisories for Great Lakes sport fish are inadequate and that consumers of those fish may face substantial excess cancer risks when tissue concentrations of DDT or dieldrin in fish are at or near the FDA action level. They may even face excess cancer risks at one-third to one-fifth of the action level if they consume fish at least weekly. By implication, advisories to restrict or avoid consumption may be necessary when tissue concentrations are one-third to one-fifth of the FDA action levels.

Several caveats apply to our modeling of risk. First, the problems inherent in extrapolation from rodent experiments to humans, the use of the multistage model, the use of benign or malignant tumors, species, sex and organ differences in tumor development rates, and the fact that DDT and dieldrin may act as promoters in the formation of cancer[16–21] may all result in inaccurate predictions of human cancer rates. The US EPA states that actual cancer rates may be much lower than the 95 per cent upper bound estimates and may actually be as low as zero. We have followed the EPA-IARC-OSTP guidelines for handling these specific points. Models are currently under development to incorporate methods of action as well as metabolic, physiologic and biochemical considerations,[22,23] but they have not been adopted or endorsed by the US EPA or FDA.

A second problem is the inconsistent data from more than 30 animal studies on the carcinogenicity of DDT, DDE and dieldrin. Even among the few studies that meet EPA-IARC-OSTP guidelines for acceptable cancer studies, not all report positive results. On the other hand, it is reassuring that the use of rats or mice and the use of DDT or DDE changes risk projections by less than one order of magnitude.

Third, the model used here may underestimate cancer risk by ignoring concurrent exposure to other contaminants.[24] Great Lakes sport fish carry several chlorinated organic contaminants in their tissues.

Fourth, the risk assessment model used here does not incorporate consideration of any benefits that may be associated with fish consumption such as reduced blood cholesterol levels and reduced risk of heart attack. Nor does it consider that proper cleaning and cooking procedures may reduce the level of some, but not all, contaminants (for example, cooking does not reduce mercury levels in fish tissue).

Finally, the risk assessment model used here does not address other toxicological endpoints. Exposure to chlorinated organic toxicants have been shown to affect visual recognition memory (PCBs),[25] motor immaturity and other neonatal endpoints (PCBs),[26] duration of breast feeding (DDE),[27] and the occurrence of chronic lymphatic leukemia (DDT).[28]

We propose that a standard, risk assessment based approach be adopted for the development of fish consumption advisories. This approach should be used to project cancer risks and combined with risk management decisions such as acceptable levels of risk and the level of acceptable economic impact, if any. This approach is appropriate until epidemiological data are available to validate current risk assessment models or until improved modeling techniques are adopted that incorporate consideration of all human health impacts as well as pharmacokinetic information, risk associated with exposure to multiple contaminants, and any risk/benefit trade-offs that are associated with consumption of sport fish.

ACKNOWLEDGMENTS

We thank M. Van Putten, K. Towler, A. Oleinick for valuable contributions to portions of this work. This work was supported in part by fellowships to M. Cox and D. Croxton from the National Wildlife Federation during graduate study at the School of Public Health, University of Michigan.

On Job/On Campus Program at U-MI SPH for Fall 1989

Public Health Policy and Administration

The University of Michigan School of Public Health will offer a new on job/on campus master's level program in "Public Health Policy and Administration" beginning in October 1989. The non-residential program features monthly sessions over an extended weekend on campus for a two-year period—modeled after the School's successful 16-year program in "Health Services Management."

The new program will focus on the development and enhancement of skills and knowledge needed for effective public health leadership in state and local public health and community health agencies. Designed for upper and mid-level managers in public health agencies as well as other community health leaders who need to expand their skills and knowledge in policy analysis, formation, and implementation, the program will emphasize integration of work experience with classroom sessions using lectures, cases, seminars, projects, and computer conferencing. Faculty will be drawn from the U-MI School of Public Health and other schools and colleges at the University, in addition to experts from both public and private institutions and programs.

For further information on this program, contact George Pickett, MD, or John Romani, PhD, Department of Public Health Policy and Administration, U-MI SPH, Ann Arbor, MI 48109-2029. Tel: (313) 764-2132.

Occupational Medicine and Industrial Hygiene

A similar program in "Occupational Medicine and Industrial Hygiene" at the U-MI School of Public Health will be offered for the fifth time in the Fall of 1989. Applications are now being accepted in the work-study program in occupational health leading to a master's degree in two years. Students attend campus once per month for three-day sessions that extend from Thursday morning through Saturday afternoon.

The Occupational Medicine and Industrial Hygiene Program includes course work in biostatistics, epidemiology, toxicology, occupational diseases, ergonomics, and industrial hygiene. For further information, contact David Garrabrant, MD, or Thomas Robins, MD, OJ/OC Occupational Health Program, School of Public Health, U-MI, Ann Arbor, MI 48109-2029. Tel: (313) 764-2594.

Public Health Briefs

Driver Age and Crash Involvement

ALLAN F. WILLIAMS, PHD, AND OLIVER CARSTEN, PHD

Abstract: The youngest and oldest drivers have the highest crash risk, but the problem lies predominantly in the youngest age groups because elderly drivers have low exposure. The elderly driver problem will increase gradually as their share of the population increases but will remain relatively small. The bulk of the problem will continue to reside among drivers younger than age 65, particularly the youngest drivers. (*Am J Public Health* 1989; 79:326–327.)

Introduction

As the average age of the population of the United States increases, attention is being given to the economic, social, and health problems that will be created or aggravated by there being more older people. The problem of motor vehicle injuries has received increased attention in this regard because the oldest drivers, along with the youngest, are known to have high crash risks when they drive.[1,2] In this paper, current relationships between age and driver crash involvement are described, and an assessment is made of the effect an aging population will have on overall driver crash rates and the contribution of various age groups to the problem during the next 40 years.

Method

The data used to compute crash involvement rates and to estimate future trends were as follows:

- Estimates of miles driven were obtained from the most recent (1983) National Personal Transportation Study (NPTS), based on a national survey of 6,438 households containing 17,382 members selected so as to represent the total civilian noninstitutional population of the United States.[3] As part of the survey all members of sampled households were asked about their travel on a randomly selected day. The data used here have been modified from the public use data supplied by the Federal Highway Administration. In the survey, many household trips were reported by someone other than the driver, and, if for some reason the driver was not subsequently interviewed, no driver trip was recorded. For such cases (about 9 per cent of all passenger car trips), no information on driver age and sex was available from the public use tapes. In the present study, the household trip data were reexamined and all driver trips are included.
- Numbers of drivers of passenger vehicles (cars, light trucks, vans) in fatal crashes were obtained from the Fatal Accident Reporting System (FARS), a computerized data base containing information on virtually all motor vehicle fatalities in the United States.[4]
- Estimated numbers of drivers of passenger vehicles in all police-reported crashes were obtained from the National Accident Sampling System (NASS), a probability sample of police-reported crashes in the United States.[5] To reduce variability from small sample sizes, three years of NASS data, 1982–84, were combined. The original national sampling weights were used, but the final estimate was divided by three to give an annual count.
- Population data (historical, present, and projected population estimates) were obtained from the US Bureau of the Census.[6–8]

Results

The youngest and oldest drivers have the highest crash rates per miles driven, both for fatal and for all crashes (Figure 1). In terms of total numbers of drivers in fatal crashes, however, the problem lies predominantly in the youngest age groups (Figure 2). Half of all drivers in fatal crashes in 1983 were 16–29 years old.

The relatively small number of elderly drivers involved in fatal crashes despite their high crash risk is attributable to three main factors: there are fewer persons per single year of age among the elderly than among younger age groups, the rate of licensure is lower among the elderly, and licensed elderly drivers drive fewer miles on average than do younger drivers (Table 1).

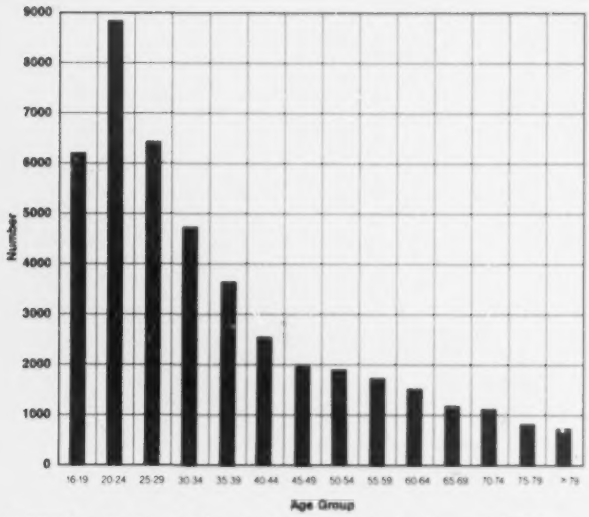

FIGURE 2—Number of Drivers in Fatal Crashes by Age Group, United States, 1983

In 1987, the 65-and-older group comprised 16 per cent of the population and 10 per cent of the drivers in fatal crashes (16.3 per 100,000 population). In contrast, 16 to 19 year-olds contributed 8 per cent of the population and 14 per cent of drivers in fatal crashes (47.1 per 100,000); 20 to 29 year-olds were 22 per cent of the population and 34 per cent of the drivers in fatal crashes (40.5 per 100,000).

The 65-and-older population is growing at a faster rate than other age groups; the result is that their population share has been increasing and will continue to do so, but the increase will be gradual until after the year 2010. In 2010, the 65-and-older group will represent 17 per cent of the population over age 15; by 2030, they will form 26 per cent of the population. However, because the age distribution is shifting such that an underrepresented group (the elderly) is becoming a larger proportion of the population and an overrepresented group (the young) is becoming a smaller proportion, if current (1987) per capita rates prevail the overall rate of drivers in fatal crashes would be lower in 2010 (24.5 per 100,000) and in 2030 (23.8) than it was in 1987 (26.5). These projected numbers indicate that in 2010 and 2030 there will be many more elderly drivers in fatal crashes, but in 2030 there would be more than twice as many 16 to 29 year-olds as 65-and-older drivers involved, and about the same number of teenage drivers as drivers over age 70.

Discussion

There has been increasing discussion of loss-reduction measures directed specifically to this age group, such as night driving curfews, special licensing actions, and driver training programs tailored to older drivers.[2,9] It is important, however, to keep the problem of elderly drivers in perspective.

TABLE 1—Per Cent Licensed and Average Annual Passenger Vehicle Miles Driven per License Holder, by Age Group, 1983

Age Group (years)	Per Cent Licensed	Average Miles Driven
16–19	61	5,199
20–29	83	8,529
30–39	92	9,748
40–49	89	9,141
50–59	88	7,679
60–69	79	5,743
70–74	41	4,463
>74	36	2,667

Older drivers have an elevated crash risk when they drive but their exposure is low; their current contribution to the problem is small and, although increasing, will remain relatively small well into the next century. The bulk of the crash problem will continue to reside with drivers younger than age 65, and particularly with the youngest drivers. Identification of effective and feasible loss-reduction measures for high-risk subgroups such as the elderly is obviously important, but these efforts should not detract from the broader goal of development and application of countermeasures aimed at drivers of all ages.

It is possible that the per capita driver fatal crash involvement rate of the elderly will increase more (or decrease less) than that of other age groups in the next decades because, among other reasons, future generations of the elderly may be relatively older or they may drive more miles. If this occurs, the contribution of the elderly will be increased, although young drivers will almost certainly continue to be the predominant group in terms of numbers involved.

ACKNOWLEDGMENT

Unintentional Deaths from Carbon Monoxide in Motor Vehicle Exhaust: West Virginia

ROY C. BARON, MD, MPH, RONALD C. BACKER, PHD, AND IRVIN M. SOPHER, DDS, MD

Abstract: We investigated the circumstances of unintended carbon monoxide deaths from motor vehicle exhaust. Of 64 episodes involving 82 deaths investigated by the West Virginia Office of the Chief Medical Examiner, 1978–84, 50 occurred outdoors in older vehicles with defective exhaust systems and 14 occurred in enclosed or semi-enclosed home garages. Blood alcohol was detected in 50 (68 per cent) of 74 victims tested; 34 had blood alcohol concentrations ≥0.10g/dl. We suggest increasing public awareness of the hazards of motor vehicle exhaust and enforcing vehicle inspection regulations. (*Am J Public Health* 1989; 79:328–330.)

Introduction

Carbon monoxide (CO) from motor vehicle exhaust is the leading cause of unintentional fatal poisoning in the United States.[1] In 1980, it accounted for 611 (14 per cent) of the nation's 4,331 unintended poisoning fatalities,[2] 2.7 deaths per 1,000,000 population. High rates are more common in northern states, in rural regions, and in areas with low per capita income.[1]

In West Virginia, which ranks second among the 50 states in rural inhabitants (63.8 per cent)[3] and 41st in per capita income ($6,141),[4] motor vehicle exhaust caused 76 (33 per cent) of the 231 unintended fatal poisonings among state residents in the years 1978–82,[5] almost three times the expected number based on the national rate in 1980 (95 per cent CI for observed/expected ratio, 2.3, 3.6).

We reviewed all unintentional deaths from CO related to motor vehicles for the years 1978–84 using data based principally from the Office of the Chief Medical Examiner (OCME).

Methods

The OCME in West Virginia has jurisdiction over all homicide, suicide, accidental, and unattended natural deaths that occur in the state and maintains a centralized file of all case records. When indicated, toxicologic analyses for blood alcohol concentration (BAC) and per cent CO saturation are performed by standard methods.[6,7]

We reviewed the OCME files for the seven-year period, 1978 through 1984, to identify all unintended deaths attributed to CO from motor vehicle exhaust. Data recorded included each victim's age, sex, BAC, and per cent CO saturation, along with the date, location, and other circumstances associated with the episode. Specific vehicle defects that might have contributed to the fatal episode were recorded from information either found in the OCME record or acquired through special request from local law enforcement agencies. The vehicles' last previous dates of inspection were not available.

A review of vital statistics for in-state deaths during 1978 (ICD-8 code E873) and 1979 through 1984 (ICD-9 code E868.2) was conducted to identify additional deaths from motor vehicle exhaust, certified as unintentional, but which had not been reported to the medical examiner. These were included only in the tabulations of age, sex, and month of occurrence since blood analyses were not performed and other details were not available.

Results

For the years 1978–84, we identified 68 separate episodes of fatal unintentional exposure to CO from motor vehicles in West Virginia, resulting in 87 deaths. Four episodes (five deaths) had not been reported to the OCME. Sixty-eight (78 per cent) decedents were male. Only one victim was a child, and rates were highest among persons 15–34 years of age, who accounted for 64 per cent of the deaths (Table 1). Episodes and deaths were most common during winter and fall and least common in late spring and summer (Figure 1). With the exception of one pick-up truck and one motorized van, all vehicles were passenger cars.

TABLE 2—Medical Examiner-Investigated Cases of Unintentional Carbon Monoxide Poisoning from Automotive Exhaust: Deaths by Location and Circumstance, West Virginia, 1978–84

Circumstance	Location					
	Outdoors		Garage		Total	
	Episodes	Deaths	Episodes	Deaths	Episodes	Deaths
Moving vehicle	4	4	0	0	4	4
Couples parked	9	17	1	2	10	19
Car repair	0	0	5	5	5	5
Stuck in snowy ditch	3	3	0	0	3	3
Other stationary vehicle	34	43	8	8	42	51*
Total	50	67	14	15	64	82

*Includes 42 persons whose prolonged car occupancy was attributed to alcohol consumption, 3 to smoking marijuana, and 2 each to conversation, use of air conditioning, or unknown.

Of the 64 episodes investigated by the OCME, 50 occurred outdoors and 14 occurred in home garages. Forty-one (76 per cent) of 54 episodes for which the information was available were estimated to have occurred between midnight and 6 am. Although not recorded routinely, car heaters were frequently reported to have been on in episodes during cooler months (September through April). Of 11 episodes that occurred during May through August, the car air conditioner had been on in at least four, and no mention of its use was recorded in the other seven.

All except four vehicles were stationary when the victims were overcome (Table 2). By available history, 42 of the 51 decedents in "other stationary" vehicles had been drinking alcohol at the time of death or were sleeping or resting in their cars after drinking earlier. Their cars were found parked in remote roadside areas (19 deaths), in empty parking lots (six deaths), outside their residences (nine deaths), or in their garages (eight deaths).

The median age of the 50 vehicles involved in outdoor episodes was 10 years (range five to 18), substantially greater than the six year median for all passenger vehicles registered in West Virginia as of July 1982.[8] Information from postmortem inspections, available for 41 of these vehicles, revealed that 40 had defective exhaust systems, with or without other body damage. Specified defects included: rust holes in the tailpipe or muffler, loose connections between the manifold and the exhaust pipe, short or missing tailpipes, and partial obstruction of tailpipes with dirt or snow. Damage noted on the car body included corrosion of the floorboards, side panels, or trunk linings.

Six of the 14 episodes in home garages occurred with the main garage door open and three others occurred with only an access door or a garage window left open. Circumstances in the remaining five garage-related episodes, ruled as accidental by the OCME, suggested that the main door had been left closed inadvertently.

Analyses performed on 74 adult decedents revealed 68 per cent with detectable BAC (Table 3), ranging up to 0.33g/dl. These included 43 (73 per cent) of 59 men and seven (47 per cent) of 15 women. In the majority of persons positive, BACs were ≥0.10 g/dl. The presence of blood alcohol was more common and observed in higher concentrations among persons found in "other stationary vehicles" than among all other decendents combined.

Discussion

Unintentional deaths from CO in motor vehicle exhaust occur year-round in West Virginia, generally in the late evening or early morning hours when people are likely to seek rest, companionship, privacy, or shelter in their automobiles. Consistent with previous reports,[9,10] most of the deaths occurred in older model vehicles that were outdoors and stationary and had badly worn, altered, rusted, or partially obstructed exhaust systems.

A majority of the garage-related episodes occurred despite open garage doors or windows, underscoring the failure of passive ventilation to be a reliable means of removing CO from semi-enclosed spaces. Since the affinity of hemoglobin for CO is approximately 220 times greater than that for oxygen,[11] even low concentrations of CO can be hazardous during prolonged exposure.

Prevention of CO deaths in motor vehicles depends, in part, on increasing public awareness of the hazards of motor vehicle occupancy while the engine is idling, particularly in older model vehicles or when the vehicle is snowbound or in semi-enclosed spaces. Drinking behavior was a predisposing factor. Since much alcohol use among victims of fatal injury is associated with problem drinking,[12] however, more ratio-

TABLE 3—Medical Examiner-Investigated Cases of Unintentional Carbon Monoxide Poisoning from Automotive Exhaust: Blood Alcohol Concentration (BAC) by Circumstance of Death, West Virginia, 1978–84

Circumstance	No. Tested for BAC	No. with Positive BAC		Total (%) Positive
		.01-.09g/dl	>.10g/dl	
Moving vehicle	3	0	1	1 (33)
Couples parked	19	5	2	7 (37)
Car repair	5	0	0	0 (0)
Stuck in snowy ditch	3	1	1	2 (67)
Other stationary vehicle	44	10	30	40 (91)
Total	74	16	34	50 (68)

nal behavior may not be a reasonable expectation. Measures to remove the hazard should be more effective than those requiring modification of behaviors or attitudes that are difficult to change or that require frequent implementation.[13]

All motor vehicles in West Virginia are required by statute to undergo an annual inspection that includes "a complete and thorough check of the exhaust system, including manifolds, gaskets, muffler, exhaust lines, brackets, and clamps." The law lists specific standards and provides for rejection if they are not met. Unfortunately, the law does not encourage compliance by requiring evidence of inspection as a condition for annual registration, and is enforced only by rare roadway spot checks for valid stickers. Furthermore, there is currently no control over the quality of the inspections.

Because we were unable to obtain the interval since last inspection, we cannot specify the number of episodes that might be averted by better compliance. Including such information as part of the routine investigation of unintended deaths from CO in motor vehicles would be important to understand the value of more effective enforcement.

The Inaccessibility of Seat Belts in Taxicabs

RONALD M. DAVIS, MD, MA

Abstract: The accessibility of seat belts was determined in a total sample of 200 taxicabs waiting to pick up passengers at eight city airports. A rear seat belt was "accessible" (able to be fastened within 10 seconds) in 111 (55.5 per cent) taxicabs. The proportion varied by city from 16.0 per cent (New York City) to 96.0 per cent (Minneapolis-St. Paul) and was higher for taxicabs in cities covered by mandatory state seat belt legislation. (*Am J Public Health* 1989; 79:330–331.)

Introduction

In 1985, there were 1.91 billion passengers in 144,235 taxicabs in the United States.[1] The safety of transportation in taxicabs could be compromised for several reasons. Taxicabs are driven an average of 52,000 miles per year,[1] a distance that might increase the risk of mechanical failure. Because of long hours on the road, taxicab drivers may be prone to fatigue, and economic incentives may encourage taxicab drivers to drive at excessive speeds. Seat belts, if present, may not function properly, or may be less accessible to passengers by falling underneath or behind the seat cushions.

There is anecdotal evidence that seat belts are inaccessible in many taxicabs.[2–4] This article describes an investigation of the accessibility of seat belts in taxicabs in eight cities.

Address reprint requests to Ronald M. Davis, MD, Director, Office on Smoking and Health, Center for Chronic Disease Prevention and Health Promotion, Centers for Disease Control, 5600 Fishers Lane, Rockville, MD 20857. This paper, submitted to the Journal May 23, 1988, was revised and accepted for publication August 3, 1988.

Methods

From May 1986 through September 1986, I assessed the accessibility of seat belts in taxicabs at a major airport in eight cities: Washington, DC (National Airport); Oklahoma City (Will Rogers World Airport); Atlanta (Hartsfield Airport); Chicago (O'Hare Airport); New York City (LaGuardia Airport); Minneapolis-St. Paul (Minneapolis-St. Paul International Airport); Ft. Lauderdale, Florida (Hollywood International Airport); and Las Vegas (McCarren International Airport). At each airport, taxicabs were randomly selected from among those waiting to pick up customers, until information had been collected for 25 taxicabs. Limousines were excluded.

I positioned myself in the rear seat of each taxicab on the far right-hand side, the most likely position to be occupied by a passenger. A seat belt was defined to be accessible if it could be fastened within 10 seconds. This was assumed to be the maximum length of time that a typical passenger would spend attempting to locate and fasten the seat belt. Seat cushions were not moved to facilitate the extraction of seat belts, but I attempted to grasp seat belts by probing between the seat cushions.

Information was collected from the drivers of the taxicabs on the year that the car was manufactured, the taxicab company, and the availability of an infant car seat for use by passengers. The existence of legislation mandating the use of seat belts among adults was also ascertained.

Miettinen test-based confidence limits were calculated for rate ratios.

Results

Information was obtained for 25 taxicabs in each of the eight cities. Seven taxicab drivers refused to participate in the study (three in Atlanta and one each in four other cities).

TABLE 1—Passenger Seat Belt Accessibility in Taxicabs in Eight Cities, United States, 1986

City	State Seat Belt Legislation*	Date of Survey	No. of Taxicabs	No. of Taxicab Companies	Median Year of Taxicab Manufacture	Taxicabs with Accessible Seat Belt**	
						No.	(%)

*Status of mandatory state seat belt legislation for adults at time of survey: A = law adopted and in effect, B = law adopted but not yet in effect, C = no legislation adopted, E = taxicabs exempted from legislation, NE = taxicabs not exempted from legislation. All existing laws in these cities affect front seat passengers only.

**See text for definition.

†Twelve taxicabs owned by different companies, 13 taxicabs privately owned.

Of the 200 taxicabs sampled, a seat belt was accessible in 111 (55.5 per cent) (Table 1). The proportion varied from 16.0 per cent in New York City to 96.0 per cent in Minneapolis-St. Paul. None of the 200 taxicabs had an infant car seat available.

Taxicabs in the four cities covered by mandatory seat belt legislation were more likely to have an accessible seat belt (76.0 per cent) than taxicabs in cities not covered by legislation (26.7 per cent) (rate ratio = 2.8, 95% confidence intervals = 2.1, 3.9). This difference is potentially confounded by the fact that the cities covered by mandatory seat belt legislation were slightly more likely than other cities to have recently manufactured taxicabs. When the cities with older taxicabs are excluded, however, taxicabs in cities covered by seat belt legislation remained more likely to have accessible seat belts (rate ratio = 4.0, 95% CI = 2.7, 6.0), although the number of cities (five) in this comparison is small.

Discussion

Only about half of all taxicabs in eight urban samples had an accessible seat belt. No data were collected on the reasons for the inaccessibility of seat belts (e.g., absent, nonfunctional, or displaced). However, in most cases seat belt straps were partially accessible or visible but the buckles were trapped behind or under the seat cushions. This suggests that the reduced accessibility of seat belts in taxicabs is caused primarily by the buckles falling (or being placed) behind or under the seat cushions. Several taxicab drivers in Las Vegas attributed seat belt inaccessibility to the fact that some drivers pull out the rear seat cushion at the end of their shift to look for money or gambling chips that passengers may have lost; this practice would allow the belts to fall under the cushions.

In 1984 and 1985, 42 fatalities of taxicab occupants were reported to the National Highway Traffic Safety Administration (Grace Hazzard, personal communication, September 25, 1986). There were 251 total occupants of the taxicabs involved in these fatal accidents. Only one (3.6 per cent) of 28 passengers using a restraint was killed, compared with 29 (21.6 per cent) of 134 passengers not using a restraint (relative risk = 6.1, 95% CI = 1.3, 30.2). (There were 12 fatalities among 89 passengers for whom restraint usage was unknown.) This pattern of increased risk with failure to use restraints is similar to that seen in all fatal motor-vehicle accidents.[5]

In 1985, there were 105.5 total nonfatal injuries and 2.7 serious nonfatal injuries for every fatality among occupants of passenger cars.[5,6] Applying these ratios to the 42 fatalities among taxicab occupants in 1984 and 1985 provides a crude estimate of 4,431 total nonfatal injuries and 113 serious nonfatal injuries among taxicab occupants. Many of these deaths and injuries could have been prevented by high occupant seat belt usage, which obviously requires the ready accessibility of seat belts.

State seat belt laws should apply to taxicabs, and should require that properly functioning seat belts be accessible and that infant car seats be available. By 1990 virtually all new cars will be equipped with rear seat lap/shoulder belts.[7] However, this will not necessarily solve the problem of inaccessible seat belts in taxicabs because the recipient portion of the belt could still fall behind or underneath the seat cushion, and because many pre-1990 models will remain on the road for several years.

Meanwhile, taxicab companies and authorities should provide signs that encourage passengers to use seat belts. All taxicabs sampled in Chicago had the following message posted next to their fares: "Please fasten seat belts: They have been installed for your safety and protection."

Coverage Gaps in Seat Belt Use Laws

JoAnn K. Wells, BA, Allan F. Williams, PhD, and Michele Fields, JD

Abstract: Some seat belt use laws exempt occupants in certain seating positions and in certain types of vehicles, or both. A state-by-state analysis was conducted of the extent to which passenger vehicle occupants killed before the laws went into effect would have been covered by the laws subsequently passed. Only five states had laws that covered all passenger vehicle occupants; the majority excluded 4 to 8 per cent and six states excluded 14 per cent or more. More inclusive laws can reduce injuries and save lives. (*Am J Public Health* 1989; 79:332–333.)

Introduction

During the four-year period 1984-87, laws requiring motor vehicle occupants to use seat belts were passed in 30 states and the District of Columbia. These laws vary from state to state in requirements, enforcement provisions, and penalties. Most states exempt some occupants from coverage even though those occupants have seat belts available for use. Some of these exemptions apply to only a few occupants (e.g., rural letter carriers and delivery vehicle drivers); others apply to far greater numbers (e.g., occupants of pickup trucks). In other countries, such exemptions have been found to limit the effectiveness of seat belt laws because use rates among the exempted populations do not increase or they increase less than in populations the laws cover.[1,2] A study of child restraint laws enacted in all 50 states between 1978 and 1985 found that nationwide about 20 per cent of the children killed in pre-law years who were within the age limits set by the subsequent laws in their state would not have been covered by the laws.[3] The present study examines the gaps in coverage of belt use laws applicable to older populations.

Method

The belt use laws enacted in 31 jurisdictions as of the end of 1987 were analyzed for coverage provisions. Using the Fatal Accident Reporting System[4] (FARS), data on motor vehicle occupant deaths were tabulated for each jurisdiction for 1980–84, the five years preceding the enactment of state belt use laws. FARS is a computerized data base containing information on virtually all fatal motor vehicle crashes in the United States. The data are collected by the state governments under contract to the National Highway Traffic Safety Administration.

Excluded from the study population were children who had already been covered by child restraint laws, occupants of any type or model year of motor vehicle not required to be equipped with seat belts, occupants in seating positions not required to be equipped with belts, and occupants of large trucks (greater than 10,000 pounds). Large trucks were excluded because, prior to implementation of the belt use law examined in the present study, interstate truckers had been required by federal regulations to use seat belts, and many states required belt use in at least some trucks traveling intrastate. The type of vehicle was obtained from FARS using the code for vehicle type and model year was determined by the variable for model year. Only these occupants in a vehicle with a known model year were used in the analysis. The data were analyzed in terms of provisions of each state law to determine how many of the fatally injured occupants would subsequently have been covered by the seat belt use laws enacted in that state. The numbers of occupants killed who would not have been covered by subsequent state laws were calculated for the various states and according to type of exemption.

Results

Six states excluded light trucks and vans as of August 1988. Twenty-six of the 31 jurisdictions exempt all rear seat occupants other than children (who had already been covered by child restraint laws); three states (Minnesota, Missouri, New York) included in their seat belt law some children older than those who had been covered by the prior child restraint law. Only five states—California, Montana, Nevada, Washington, and Wisconsin—cover all passenger vehicle occupants.

Table 1 shows for each jurisdiction the total number of passenger vehicle occupant deaths in 1980-84, the number who would not have been covered by the subsequent state law because of exemptions for occupants in rear seats or for occupants of light trucks and vans, and the total number and per cent exempted.

In the 31 jurisdictions combined, 8,064 (7.6 per cent) of the motor vehicle occupants killed in 1980-84 would not have been covered by the subsequent state laws; 5,579 (5.3 per cent) of these were because of the rear seat exemption, and 2,485 (2.4 per cent) were because of the light truck and van exemption. In most states with seat belt laws (20), 4 to 8 per cent were exempted. However, in the six states that exempt light trucks and vans (all of which also exempt rear seat occupants), the per cent exempted ranged from 14 to 40. New Mexico (40 per cent), Oklahoma (33 per cent), and Missouri (25 per cent) have the highest exemption rates.

There is some limited evidence that exempted occupants do not increase their belt use to the same extent as occupants covered by the laws. Most state observational surveys of belt use have been restricted to front seat occupants and do not distinguish vehicle type. However, data from New Mexico show that seat belt use in passenger cars increased from 29 per cent before the law to 53 per cent early in the law's first year and was 46 per cent two years later. In contrast, belt use in pickup trucks in New Mexico was 19 per cent before the law, 24 per cent right after, and 18 per cent two years later.[5] In Texas, where both cars and pickup trucks are covered, belt use increased in both. Among car occupants, belt use was 16 per cent before the law, 64 per cent right after, and 56 per cent two years after the law. In Texas, 9 per cent of pickup truck occupants used seat belts before the law, compared to 49 per cent right after, and 43 per cent at the two-year mark.*

*Oklahoma amended its seat belt law effective March 1, 1989 to include pickup trucks and vans.

Discussion

Seat belt use laws in the United States have been shown to be somewhat effective in increasing belt use and reducing injuries and fatalities.[6,7] However, their potential effectiveness is limited in part by excluding from coverage some vehicle occupants who have seat belts available for use. Because this study analyzed fatalities that occurred during the period when no seat belt laws were enacted, it does not measure the efficacy of seat belt use laws once in force, but it does illustrate that more of the population could have been included under the laws. Although most states have laws that would have applied to more than 90 per cent of the motor vehicle occupants killed in their states in the years just before the laws were passed, a few states—those that exempt light truck and van occupants but have many of these vehicles on their roads—exclude 25 to 40 per cent of their occupant population. The gaps in coverage may have arisen because of political exigencies in passing the laws, but they have no logical basis. Some of the gaps in coverage that existed in the original child restraint laws have been removed through amendments. Louisiana has amended its belt use law effective August 1, 1988 and Oklahoma amended its law effective March 1, 1989 to include vans and pickups. Similar amendments in other states would very likely increase the laws' effectiveness and save lives.

Johns Hopkins Injury Prevention Center Invites Nominations for 1989 Award of Excellence

In 1988 the Johns Hopkins Injury Prevention Center established the Award of Excellence to recognize and honor one or more individuals each year who have made substantial contributions to the prevention of injuries. Any person who has made significant achievements in the prevention of injuries, whether through research, policy formulation, advocacy, or other means is eligible for the award.

Garen J. Wintemute, MD, MPH, Assistant Professor of Family Practice at the University of California-Davis, was chosen as the first recipient in recognition of his work on the prevention of firearm injuries. The award was presented during a ceremony at the Johns Hopkins School of Hygiene and Public Health on October 26, 1988.

Nominations are invited for the second annual Award of Excellence, to be presented in the fall of 1989. Letters of nomination should include a description of the nominee's contributions to injury prevention and the significance of the nominee's achievements. A curriculum vitae of the nominee should accompany the nomination. Send nominations to:

Reducing Knee Morbidity among Carpetlayers

SHIRO TANAKA, MD, MS, SHIU T. LEE, MS, WILLIAM E. HALPERIN, MD, MPH, MICHAEL THUN, MD, MS, AND A. BLAIR SMITH, MD, MS

Abstract: Carpetlayers have a high prevalence of occupational knee morbidity, partly attributable to their use of the knee kicker to stretch carpet for wall-to-wall installation. While a mechanical alternative "power stretcher" is available, knee kickers are still widely used. A questionnaire survey indicated that unavailability of the mechanical stretcher at installation sites was a major factor for continued use of the knee kicker. Strategies to reduce use of the knee kicker are discussed. (*Am J Public Health* 1989; 79:334–335.)

Introduction

There are approximately 99,000 carpetlayers in the United States.[1] They file workers' compensation claims 108 times more than expected[2] for "knee joint inflammation attributed to kneeling, striking against a stationary object, etc." Both kneeling and use of the knee kicker were significantly related to their knee morbidity.[3]

A knee kicker is made of cast aluminum and weighs about 2 kg. Every carpetlayer owns one. To stretch carpet, it is pressed onto carpet by a hand and its padded end is kicked with the suprapatellar area. The average impact force exceeds 3,000 Newtons repeated about 140 times per hour[4] (Figure 1).

As an alternative, a mechanical stretcher using the lever and cogs is available. It weighs about 20 kg by itself; the total weight with accessories and the case may reach 40 kg (Figure 2). Customarily, it is provided by employers (contractor or carpet dealer) and assembled for on-site use. We examined the reasons for carpetlayers choosing between these two devices.

Method

As part of a health hazard evaluation on carpetlayer's knee problems, pertinent questions were included in a self-administered questionnaire to assess their use of the mechanical stretcher and subjective evaluation of the tool. The questionnaire was mailed to members of the local floorlayers union; only those who "have ever used a mechanical stretcher" were instructed to proceed with the subsequent questions.

Respondents were asked to estimate the ratio of using the two carpet stretching devices. Questions concerning the attributes of the mechanical stretcher included the ease of use, portability, safety to the knee, speed and quality of carpet installation, and availability at job sites. For each attribute, respondents were asked to choose one of four graded responses about the device with an implied comparison to the knee kicker.

From the Division of Surveillance, Hazard Evaluations and Field Studies, National Institute for Occupational Safety and Health, Cincinnati, Ohio. This paper, submitted to the Journal May 6, 1988, was revised and accepted for publication August 29, 1988.

FIGURE 1—A Carpetlayer Using a Knee Kicker

Results

One hundred and thirty-two (78 per cent) of 170 union members returned the questionnaire. The local union included subsets of other tradesmen, such as interior decorators, whom we excluded from our analysis, restricting it to the 94 (71 per cent) of respondents who reported ever using a mechanical stretcher. All respondents were males; 47 per cent used the knee kicker more often, 20 per cent used both tools about equally, and 33 per cent used the mechanical stretcher more often. Mean ages were similar in these three groups.

The majority of respondents reported that the mechanical device was easy to use, "saved" the knees, and achieved a better quality of installation more quickly (Table 1). However, almost 60 per cent said it was difficult to carry around; about one-third felt that it slowed down the job, and 39 per cent reported it was not always available at the job site.

FIGURE 2—A Carpetlayer Using a Mechanical Stretcher

TABLE 1—Favorable or Unfavorable Attributes of the Mechanical Stretcher (MS) with Implied Comparison to the Knee Kicker

Mechanical Stretcher (is):	Very Favorable About MS %*	Somewhat Favorable about MS %	Somewhat unfavorable about MS %	Very Unfavorable About MS %	Mechanical Stretcher (is):
Easy to use	47.9[a]	45.7[b]	6.4[c]	0[d]	Difficult to use
Easy to carry around	7.4	33.0	41.5	18.1	Difficult to carry around
Saves my knees	71.3	24.5	4.2	0	Harmful to my knees
Helpful in doing a quick job	33.0	34.0	29.8	3.2	Slows down my job
Helpful in doing a better job	87.2	9.6	3.2	0	Not as good as knee kicker
Available	60.7[e]	22.3[f]	17.0[g]	0[h]	Unavailable

*Percentages of each row add up to 100%.
a) Very easy, b) fairly easy, c) fairly difficult, or d) very difficult *to use.*
e) Always, f) usually, g) sometimes, or h) never *available.*

A logistic regression analysis showed that the "availability" and "save knee" factors were associated with the increased use of the mechanical stretcher.*

Discussion

Why do carpetlayers continue to use the knee kickers which are traumatic to their knees while a safer alternative is available?

Observation of carpet installation reveals that the knee kicker is kicked with two different intensities—mild and strong. Milder kicks are applied initially to engage the edge of carpet onto the tacks (which have been nailed to the perimeter of the floor), or when installing carpet in small confined spaces such as a closet.[4] In contrast, very forceful kicks are applied in normal installations to get a good stretch. The latter is likely to be most harmful to the knee, and should be totally replaced by using the mechanical stretcher. This survey sheds some light onto what could be done to increase the use of the mechanical device and reduce the use of the knee kicker.

The perceived shortcomings of the mechanical stretcher were: unavailability at the job sites, difficult portability (heavy and bulky), and cumbersome to use. The unavailability or non-use factor may be due to the initial higher cost of the mechanical stretcher ($400) compared to the knee kicker ($75) or failure of an employer to provide enough of the mechanical stretchers for each work crew to use; another economic factor might be that, if use of the mechanical stretcher slowed down the speed of installation for some carpetlayers, the employer would be reluctant to encourage its use.

*Availability: O.R. = 2.27, 95% CI = (1.35, 3.85); "Save" knee: O.R. 2.04, 95% CI = (1.02, 4.17); The questionnaire, detailed tabulations, and regression analysis data will be provided upon request to the first author.

Several strategies are suggested to increase the use of the mechanical stretcher:

- Building contractors, carpet dealers and trade unions could initiate or intensify educational efforts to emphasize the potential health hazard of using the knee kickers and encourage carpetlayers to rely more on the mechanical stretcher.
- Carpetlayers could be trained to become proficient in using the mechanical stretcher regardless of the room size.
- Employers should be encouraged to provide an adequate number of mechanical stretchers for each work crew.
- The portability issue could be addressed by such engineering approaches as attaching casters to the carrying case, or inventing a light-weight pneumatic stretching device.
- Consumers could be educated about the health hazards of the knee kicker and encouraged to specify the use of the mechanical stretcher for quality installation.
- A regulatory requirement could stipulate that employers provide each carpetlayer with a mechanical stretcher at job sites.

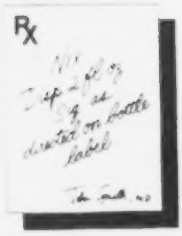
CREME RINSE
permethrin 1%



PEDICULICIDAL/OVICIDAL ACTIVITIES: *In vitro* data indicate that permethrin has pediculicidal and ovicidal activity against *Pediculus humanus* var. *capitis*. The high cure rate (97-99%) of Nix in patients with head lice demonstrated at 14 days following a single application is attributable to a combination of its pediculicidal and ovicidal activities and its residual persistence on the hair which may also prevent reinfestation.

INDICATIONS AND USAGE: Nix is indicated for the single-application treatment of infestation with *Pediculus humanus* var. *capitis* (the head louse) and its nits (eggs). Retreatment for recurrences is required in less than 1% of patients since the ovicidal activity may be supplemented by residual persistence in the hair. If live lice are observed after at least seven days following the initial application, a second application can be given.

CONTRAINDICATIONS: Nix is contraindicated in patients with known hypersensitivity to any of its components, to any synthetic pyrethroid or pyrethrin, or to chrysanthemums.

WARNING: If hypersensitivity to Nix occurs, discontinue use.

PRECAUTIONS:

General: Head lice infestation is often accompanied by pruritus, erythema, and edema. Treatment with Nix may temporarily exacerbate these conditions.

Information for Patients: Patients with head lice should be advised that itching, redness, or swelling of the scalp may occur after application of Nix. If irritation persists, they should consult their physician. Nix is not irritating to the eyes; however, patients should be advised to avoid contact with eyes during application and to flush with water immediately if Nix gets in the eyes. In order to prevent accidental ingestion by children, the remaining contents of Nix should be discarded after use.

Combing of nits following treatment with Nix is not necessary for effective treatment. However, patients may do so for cosmetic or other reasons. The nits are easily combed from the hair treated with Nix after drying.

Carcinogenesis, Mutagenesis, Impairment of Fertility: Six carcinogenicity bioassays were evaluated with permethrin, three each in rats and mice. No tumorigenicity was seen in the rat studies. However, species-specific increases in pulmonary adenomas, a common benign tumor of mice of high spontaneous background incidence, were seen in the three mouse studies. In one of these studies there was an increased incidence of pulmonary alveolar-cell carcinomas and benign liver adenomas only in female mice when permethrin was given in their food at a concentration of 5000 ppm. Mutagenicity assays, which give useful correlative data for interpreting results from carcinogenicity bioassays in rodents, were negative. Permethrin showed no evidence of mutagenic potential in a battery of *in vitro* and *in vivo* genetic toxicity studies. Permethrin did not have any adverse effect on reproductive function at a dose of 180 mg/kg/day orally in a three-generation rat study.

Pregnancy: *Teratogenic Effects*: Pregnancy Category B. Reproduction studies have been performed in mice, rats, and rabbits (200-400 mg/kg/day orally) and have revealed no evidence of impaired fertility or harm to the fetus due to permethrin. There are, however, no adequate and well-controlled studies in pregnant women. Because animal reproduction studies are not always predictive of human response, this drug should be used during pregnancy only if clearly needed.

Nursing Mothers: It is not known whether this drug is excreted in human milk. Because many drugs are excreted in human milk and because of the evidence for tumorigenic potential of permethrin in animal studies, consideration should be given to discontinuing nursing temporarily or withholding the drug while the mother is nursing.

Pediatric Use: Nix is safe and effective in children two years of age and older. Safety and effectiveness in children less than two years of age have not been established.

ADVERSE REACTIONS: The most frequent adverse reaction to Nix is pruritus. This is usually a consequence of head lice infestation itself, but may be temporarily aggravated following treatment with Nix. 5.9% of patients in clinical studies experienced mild temporary itching; 3.4% experienced mild transient burning/stinging, tingling, numbness, or scalp discomfort; and 2.1% experienced mild transient erythema, edema, or rash of the scalp.

DOSAGE AND ADMINISTRATION:

Adults and Children: Nix is intended for use after the hair has been washed with shampoo, rinsed with water and towel dried. Apply a sufficient volume of Nix to saturate the hair and scalp. Nix should remain on the hair for 10 minutes before being rinsed off with water. A single treatment is sufficient to eliminate head lice infestation. Combing of nits is not required for therapeutic efficacy, but may be done for cosmetic or other reasons.

SHAKE WELL BEFORE USING.

HOW SUPPLIED: Nix (Permethrin) 1% (wt./wt.) Creme Rinse is supplied in plastic squeeze bottles that contain 2 fl. oz. weighing 56 g. (NDC-0081-0780-81).

Store at 15°-25°C (59°-77°F).

Health Effects of the War in Two Rural Communities in Nicaragua

Nicaragua Health Study Collaborative at Harvard, CIES,* and UNAN†

Abstract: We report on a pilot study to assess the effects of low intensity war in Nicaragua on the health of the civilian population. The study compared data from two regions in Nicaragua, one in an area of intense conflict, the other further removed from the war's violence. Information was obtained from a questionnaire administered to female heads of randomly selected households; structured interviews with community leaders and health workers; group discussions with community residents; and a review of regional and municipal death records. Height and mid-upper arm circumference of children were measured, and immunization records reviewed.

The war has had a serious negative effect on the lives of the civilian population in both the war zone and the non-war zone, with the effects most severe in the war zone. In both communities, over half of the respondents reported the death of a friend or relative. In the war zone community, over one-fourth of respondents reported attacks on family members in non-combat situations around their homes. Death by firearms was the leading cause of death in persons over age 6 in the war zone. Vaccination coverage, nutritional indices, and familial disruption were worse in the war zone community. The findings suggest that continued funding of the Nicaraguan *contra* forces by the United States may be harming the ostensible beneficiaries of that policy, and that use of such low intensity conflict as a foreign policy tool should be questioned. (*Am J Public Health* 1989; 79:424–429.)

Introduction

There has been a dramatic and well-documented improvement in the health status of the Nicaraguan population since the revolution of July 1979.[1–11] The war waged by counterrevolutionary forces (*contras*) attempting to overthrow the government of Nicaragua has threatened to halt or reverse these advances. The contra war in Nicaragua is an example of what is termed "low intensity conflict" (LIC) by United States military and diplomatic officials.[12–14] LIC refers to conflicts short of conventional war, which intentionally subject the civilian population to a combination of psychological, economic, and military pressure to promote the adoption of the desired social system by the civilian population.

Several reports, using national data and standard epidemiologic methods, have documented negative effects of the current war in Nicaragua on the health status of the civilian population.[10,15–17] To date, however, little field research has examined the effects of the war through the collection of data at the community level. We report here the results of a pilot study comparing health indicators collected in a uniform fashion in two regions in Nicaragua, one in an area of intense conflict, the other further removed from the violence of the war.

Methods

Data were collected on selected health indicators in two regions of Nicaragua: one suffering frequent *contra* attacks and another experiencing fewer contra attacks to serve as a comparison. For this pilot study, a single town was chosen in each region as representative of the region under study.

Information was obtained from four sources:

- A questionnaire administered to the female heads (*amas de casa*) of a random sample of households with at least one child under 6 years of age;
- Standardized interviews conducted with community leaders: health professionals, the mayor, school teachers, and the head of the women's organization;
- Facilitated group discussions;
- Review of municipal and regional death records.

Regional information was obtained in structured interviews with Ministry of Health officials and from annual health records.

The household questionnaire measured a variety of health indicators, including economic conditions, food availability, nutrition, child health, stability of family life, disruption or deaths due to the war, access to health services, educational status, and psychological health. Vaccination data were recorded on all children under 72 months of age whose vaccination cards were available. Standing height of all children of the household between the ages 24 and 71 months present during the interview was measured using a metal tape measure and right angle. Mid-upper arm circumference of the left arm of children between 12 and 71 months was measured using an insertion-type measuring tape.[18]

Towns to be studied were selected from Nicaragua's Region V, an area in the central part of the country under increasing attack from the *contras* since 1984,[19] and from Region IV, an area on the Pacific Coast near the Costa Rican border. According to the Ministry of Health, Region IV has experienced only isolated *contra* attacks since the Revolution in 1979.

In Region V, we studied the town of Acoyapa. A community of about 8,500 population, and surrounded by nine small villages or *comarcas*, Acoyapa is located in the dry, hilly region of Chontales Province east of Lake Nicaragua, about 30 kilometers by paved and fairly secure road from the provincial capital, Juigalpa. While Acoyapa itself has not been subjected to a direct *contra* attack, the mayor reported there have been at least 10 attacks on the surrounding *comarcas*, and fighting has occurred within a few kilometers of the town.

El Ostional was selected as the comparison town from Region IV. A town of 441 residents, and also surrounded by neighboring *comarcas*, El Ostional is a fishing and farming community located on the southern Pacific coast of Nicaragua, 12 kilometers from the Costa Rican border and 30 kilometers by dirt road from San Juan del Sur, the nearest town with over 2,000 population.

Despite the difference in their sizes, Acoyapa and El Ostional are similar in several important aspects. The economies of both towns are based on food production, and both towns have health facilities with a permanent staff.

El Ostional and two towns in Region V of comparable size, economy, and proximity to a major road or city were pre-selected jointly by the Ministry of Health and the North American study participants. Arriving in the war zone in Region V, however, the team was informed by the regional Ministry of Health that one of the pre-selected towns had been attacked just 10 days earlier and that the road leading to the other town had been mined by the *contras*. Considerations of safety led to the final choice of Acoyapa on the day the study began.

The field work and data collection were conducted in January and February 1987 by 11 North Americans, five in the war zone and six in the non-war zone. Random samples of households were surveyed in both towns. The female head of household was defined as the woman within the household identifying herself to be the ama de casa. In Acoyapa, a group discussion was conducted with families of displaced persons. In El Ostional, all the women in the town were invited to participate in a group interview.

Results

Sample Survey

Fifty interviews were completed in 76 sampled households in Acoyapa. Thirty-nine interviews were completed in 59 sampled households in El Ostional. The selected households represented approximately 9 per cent of households in Acoyapa and 90 percent of households in El Ostional. Interviews were not conducted in sampled households if the female head of household was not home on three successive visits, or if no children under age 6 lived in the home. No interviews were refused in either community.

The two towns were similar economically, with nearly identical proportions of households having electricity (78 and 82 per cent in Acoyapa and El Ostional respectively), radio or television (50 and 51 per cent), and a latrine (84 and 82 per cent). Only half of the households in Acoyapa had piped water compared to 84 per cent in El Ostional. At the time of the investigation, however, the actual flow of water was disrupted in both communities due to malfunctioning pumping systems and parts being difficult to obtain because of the economic embargo. Houses in both communities were small and crowded, with a mean of about 4.5 occupants per room in both. A mean of roughly 2.5 children under 6 years of age per household was reported in both towns, although the mean number of occupants in Acoyapa was 10.7 compared to 7.8 in El Ostional.

Respondents were asked if their standard of living was better, worse, or the same as the year before. In Acoyapa (war zone), half (51 per cent) of the households reported their living standard currently *worse* than the year before compared to 41 per cent in El Ostional, while only 8 per cent in Acoyapa reported an *improved* living standard compared to 26 per cent in El Ostional (test for trend $\chi^2 = 3.13$, df = 1, p = .077).

Indices of change in food production, change in food availability, and nutrition were consistently worse in Acoyapa (war zone) than in El Ostional (non-war zone). Eighteen per cent (9 of 50) of the households in the war zone town had had one or more members leave agricultural production within the past year, compared to none (0 of 39) in El Ostional (95% CI = 1.7,∞).

As an indicator of availability of food, respondents were asked whether they were eating more, the same, or less of three basic starch foods and seven basic protein foods than the year before. A greater proportion of people in Acoyapa reported eating less rice, corn, chicken, milk, cheese, and fish, and fewer eggs and beans compared to the year before than in El Ostional (Table 1). Starch consumption had decreased in both communities, while protein consumption had decreased greatly only in Acoyapa (Figure 1). Consumption of both starch and protein foods had declined significantly more in the past year in Acoyapa than in El Ostional (Wilcoxon rank sum test: for starch foods $z = 3.04$, $p = .002$; for protein foods $z = 4.86$, $p < .0001$).

Prevalence of chronic undernutrition in children ages 24 to 71 months as estimated by the proportion of children with height for age below the 5th percentile* compared to the National Center for Health Statistics reference popula-

TABLE 1—Comparison of Change in Consumption of Basic Foods over Previous Year

Food	Number (per cent) of Households Eating Less of Food Item		Odds Ratio	95% CI
	Acoyapa	El Ostional		
Starches				
Corn	33 49 (67)	14 38 (37)	3.54	(1.45, 8.60)
Rice	38 49 (78)	22 38 (58)	2.51	(1.0, 6.37)
Plantains	21 48 (44)	11 38 (29)	1.39	(.58, 3.37)
Proteins				
Milk	27 49 (55)	7 38 (18)	5.44	(2.01, 14.7)
Eggs	21 49 (43)	5 38 (13)	4.95	(1.65, 14.8)
Beans	30 49 (61)	13 37 (35)	2.91	(1.20, 7.07)
Chicken	18 49 (37)	6 38 (16)	3.10	(1.09, 8.83)
Cheese	19 49 (39)	7 38 (18)	2.80	(1.03, 7.64)
Fish	11 47 (23)	2 36 (6)	5.19	(1.07, 25.2)
Red Meat	28 49 (57)	16 38 (42)	1.83	(.78, 4.32)

The analysis was done by comparing the proportion of households reporting eating less of a particular food to the proportion giving any of the other possible responses. Other possible responses were that the respondent eats more or the same of the food as the year before, or the respondent does not eat the food at all.

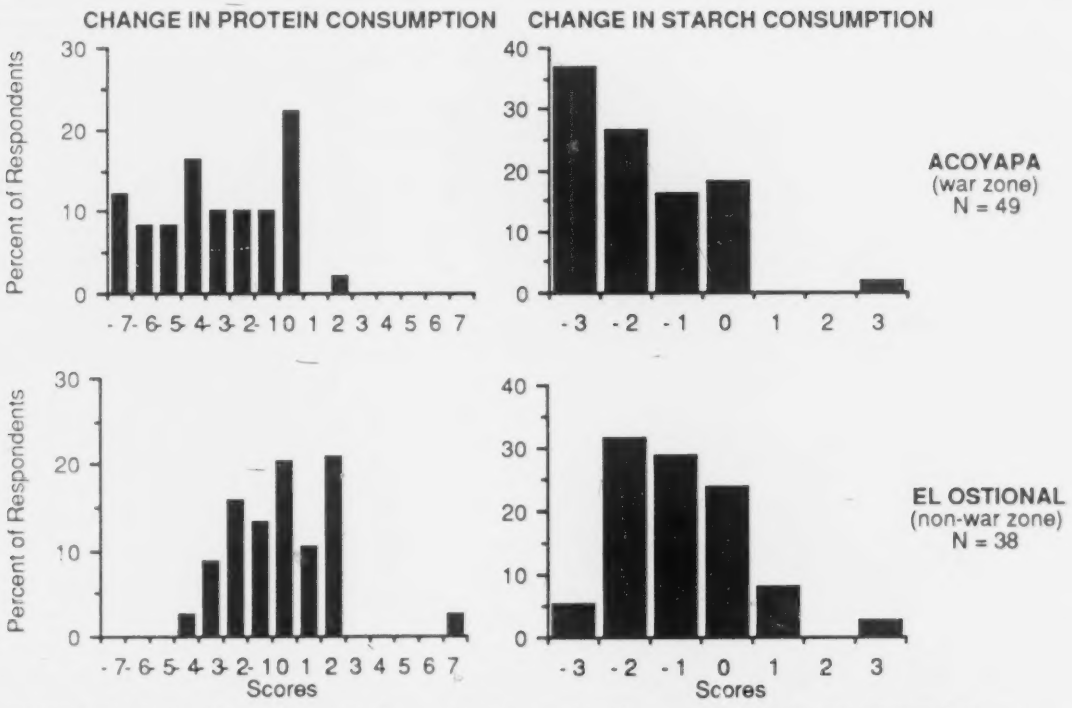

FIGURE 1—Distribution of households reporting increase, decrease, or no change in consumption level of protein and starch foods. To assess overall change in consumption of starch and protein foods, composite scores for change in both were constructed for each household. Integer values were assigned to responses for individual foods, and separately summed for the three starch foods and the seven protein foods. The response 'more' was scored with 1, 'less' with −1, and 'same' or 'not at all' with 0. Thus, starch scores range from −3 to 3 and protein scores from −7 to 7. Negative scores indicate a net decline in consumption of the seven protein and three starch foods investigated. Note the difference between towns in the proportion of households with protein scores −7 to −4 and with the worst starch score of −3.

tion[20-22] was greater in Acoyapa than in El Ostional. In Acoyapa (war zone), 22 of 50 children (44 per cent) were below the 5th percentile compared to 9 of 47 (19 per cent) in El Ostional (non-war zone) (OR = 3.32, 95% CI = 1.33, 8.29). Although many children in both towns showed signs of chronic undernutrition, none of the 81 children ages 12 to 71 months measured in Acoyapa and none of the 69 children measured in El Ostional exhibited signs of severe acute undernutrition as indicated by a mid-upper arm circumference less than 12.5 cm.[23-25]

Vaccination coverage was better in the non-war zone town than in the war zone town, based on both recorded completeness of vaccination and a crude measure of possession of an immunization card as a proxy for coverage.* In only 20 of 50 households (40 per cent) in Acoyapa compared to 29 of 39 (74.4 per cent) in El Ostional, immunization cards were presented for all children under 6 years of age in the household (OR = .23, 95% CI = .09, .57). Only 18 of 48 (37.5 per cent) children between the ages of 12 and 71 months with vaccination cards were completely vaccinated in Acoyapa compared to 47 of 60 (78 per cent) in El Ostional (OR = .17, 95% CI = .07, .39) (Table 2). A child was considered completely vaccinated if he or she had three recorded doses of DPT, three polio, 1 measles, and either a written record or scar for BCG.

Comparison of the immunization coverage shown in Table 2 with levels in 1980 shows that despite the war, considerable advances have been made. In 1980, the per cent of children one year old who were immunized was 50 per cent with BCG, 18 per cent with DPT, 18 per cent against polio, and 15 per cent against measles.[26]

Families in both Acoyapa and El Ostional have experienced violence as a result of the war. In both communities, over half of the respondents had experienced the death of a friend or relative, while one-fifth reported a member of the household killed, kidnapped, or wounded.

In Acoyapa (war zone), of the 26 respondents reporting that members of the family in the same household or relatives living in other households had been attacked or killed in the war, 14 indicated that the violence was done to non-

TABLE 2—Completeness of Vaccination Coverage in Children Ages 12–72 Months by Town

Vaccination	Number (Percentage) of children with complete vaccination*		Odds Ratio	95% CI
	Acoyapa n = 48	El Ostional n = 60		
All vaccinations complete	18 (38)	47 (78)	.17	(.07, .39)
3 DPT	19 (40)	56 (93)	.05	(.01, .15)
3 Polio	39 (48)	57 (95)	.23	(.06, .90)
1 Measles	35 (73)	51 (85)	.48	(.18, 1.28)
1 BCG	35 (73)	60 (100)	—	(−∞, .07)

*Sample excludes children who had no vaccination card

*Immunization cards are commonly kept in each child's house, in addition to records kept in the health centers.

combatant civilians in and around their homes. Of these, 13 were attributed to the *contras* and one was attributed to cross-fire between government forces and the *contras*. Two nieces of one respondent, both under 15 years of age, were kidnapped by the *contra* and still missing at the time of the interview. In one case, the *contra* murdered 11 male cousins and one of their wives at a family party, the respondent thought because of their cooperation with governmental agricultural extensionists. In another case, seven adults were wounded by the *contras*. In one incident, a man crossing lines of fire between the government forces and the *contra* was, according to the respondent, accidentally shot. No similar reports of violence against civilian relatives were offered in El Ostional.

The proportion of households in Acoyapa with children under 14 years of age missing at least one parent due to the war (17 per cent) was twice that observed in El Ostional (8 per cent) (OR = 2.32, 95% CI = .57, 9.47).

Mobility was high in both communities, with 16 per cent of the households in El Ostional and 21 per cent in Acoyapa reporting people moving in within the last year. Thirteen per cent of the households in El Ostional and 24 per cent in Acoyapa had people moving out within the past year. While none of the mobility in El Ostional was reported to be directly related to the war, half of the movement in Acoyapa was due to the war. A larger proportion of the *amas de casa* in Acoyapa (22.4 per cent) had lived in the town for less than three years than in El Ostional (8 per cent) (OR = 3.28, 95% CI = .84, 12.8).

Municipal Death Records

Review of the Municipal Registry of Acoyapa revealed that death by firearms was the leading cause of reported deaths in persons over 6 years of age in 1986, with a marked increase in death by firearms since 1984 (Figure 2). The municipality of El Ostional had no comparable registry. In Region IV, which includes El Ostional, records kept by the regional Ministry of Health showed death from firearms to be the fourth leading cause of reported deaths in persons over 6 years of age in both 1985 and 1986.

Regional Interviews and Records

The two regions studied differ greatly in the extent to which their primary health care systems have been affected by the *contra* war (Table 3). Ministry of Health records showed that in Region V (war zone), 20 health posts and health centers functioning in 1983 have been either destroyed, attacked, or closed due to the *contra* threat to health workers providing services there. By contrast, in Region IV (non-war zone), all of the clinics functioning in 1983 continue to provide services today.

The war has also affected programs of preventable disease control in Region V. Since 1984, five of ten health areas (administrative sub-divisions of the health region) in Region V have not been able to participate fully in the three campaigns held each year to administer measles, DPT, and polio vaccines to children. Half of the areas of Region V have also been unable to participate in the national malaria control campaign.

Community Interviews

In Acoyapa, civilians engaged in health and education work in the rural areas surrounding the town have been subject to attack by the *contra*. Health workers and teachers reported that at one health post, an auxiliary nurse was killed, and another salaried health worker threatened at gunpoint. Of

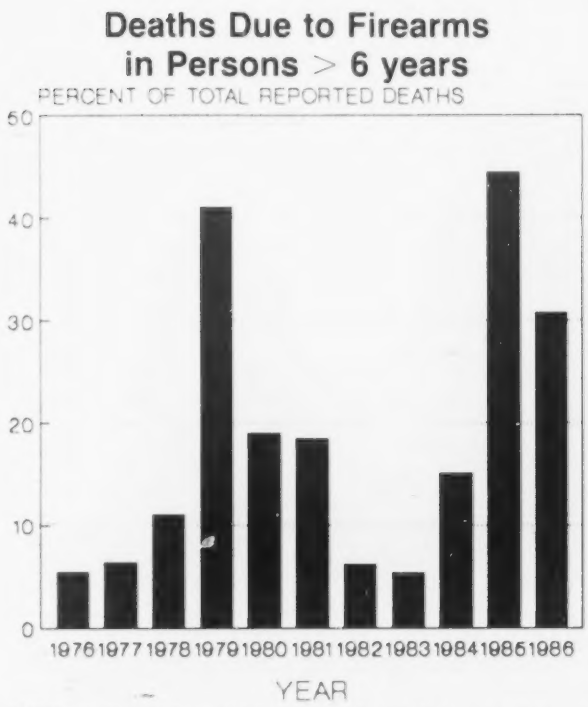

FIGURE 2—Percent of reported deaths due to firearms in persons over 6 years of age in the Municipality of Acoyapa (war zone) from 1976 to 1986. Absolute figures are 1976: 2/36; 1977: 2/31; 1978: 3/26; 1979: 14/34; 1980: 6/31; 1981: 7/38; 1982: 2/32; 1983: 2/38; 1984: 6/40; 1985: 24/54; 1986: 8/26. Source: Municipal Death Records Acoyapa.

TABLE 3—Regional Effects of the War

Health Service	Region V (war zone)	Region IV (non-war zone)
Health clinics:		
destroyed since 1984	3	0

the 20 brigadistas (community health workers) serving the nine *comarcas*, ten have been kidnapped and five have quit due to the threat. Mobile clinics have been stopped and no vaccination campaigns occurred in 1986. Vaccination campaigns under the protection of army escort were planned for 1987. Four teachers in one of the *comarcas* near Acoyapa were threatened by the *contra*, and three requested transfers to other areas. The ongoing adult literacy campaign in the countryside has been discontinued due to this threat of violence.

The economic infrastructure of the area also has been affected by the war. According to the food distribution coordinator in Acoyapa, some 1,300 people moved into the town from its war-torn surroundings from 1983 to 1986. The market in Acoyapa where local producers used to sell their

food no longer takes place because people are too afraid to travel the roads frequently.

A group discussion with displaced persons from 20 different families in Acoyapa produced numerous reports of attacks on health and education facilities, as well as on civilians by the *contras*. These included the burning of an elementary school, an agricultural cooperative and two homes, the kidnapping of 14 people (including seven children), and the killing of at least ten people. An attack on a health center resulted in it, as well as the school, being closed.

The interviews with community leaders and the group discussion with women in El Ostional (non-war zone) showed that while that community has not been subject to armed conflict since the insurrection of 1978-79, the war has been felt in less direct ways. The area was shelled once from the sea in 1985. With the escalation of the war in 1983, the nearby border with Costa Rica was closed, ending the active trade that had existed between communities on either side of the border, and affecting availability of basic goods. Scarcity of resources has prevented the planned construction of a fish packing plant and child care center. Teachers reported young children in their classes expressing fear of violent death at the hands of the *contra*. Trenches have been dug around the health post to defend it from attack. The adult education supervisor reported there are areas in the region to which she no longer travels for fear of *contra* attack. In the group discussion with 35 women from El Ostional, mothers spoke extensively of their anxiety that their families would be harmed by the *contra*, or that they would not be able to adequately feed their families due to economic problems created by the war.

Discussion

The findings of this study provide a consistent picture of the damaging effects of the war on the civilian population in Nicaragua, especially in the war zone. Reports of deliberate targeting of health, education, and food production facilities by the *contras* are particularly apparent. Regional Ministry of Health officials in the war zone described a pattern of *contra* attacks on food production and transport facilities, as well as on the health care infrastructure. Community leaders and displaced persons interviewed in the war zone reported *contra* attacks on agricultural cooperatives, small farms, clinics, and individual health care and education workers in the countryside surrounding Acoyapa, the war-zone community. More than a fourth of the surveyed households in Acoyapa reported attacks on family members or relatives in non-combat situations in or around the families' homes. Attacks in the countryside are forcing people to leave subsistence farming, a principle source of food, and the population of Acoyapa has grown by 15 per cent in the past four years. Municipal death records show a marked increase in the firearm-related death rate among civilians in the Municipality of Acoyapa since 1984.

This study was a pilot of a method to assess the effects of low intensity conflict on the lives of a civilian population at the community level. The comparison of a community-based household survey in the war zone to one in the non-war zone was designed to measure the direct effects of *contra* or other combat activity on the civilian population. The method of random sampling was chosen to avoid possible bias in the respondents. Despite the relatively small number of households interviewed, a consistent pattern of more persons being forced from agriculture, worsening availability of food with attendant greater prevalence of chronic undernutrition, poorer vaccination coverage, a greater decline in the standard of living, as well as a greater direct experience of violence against civilians in the war zone emerges from the results of the household survey. The low prevalence of severe acute undernutrition in both towns suggests that existing food distribution systems, which include a government rationing system for staple commodities, have prevented frank starvation.

Several methodological problems limit interpretation of the comparative results of the sample survey. Generalizability of the results from the communities to their respective regions is limited because of the one-to-one comparison of the towns and the non-random selection of the communities to be studied. Differences in a one-to-one comparison may be due to many different factors, and particularly in this case to the difference in size of the towns studied. Information gathered from the other sources is, however, consistent with an interpretation that the differences are due to the war. Safety considerations prevented implementation of the original plan to study more than one town in the war zone and to study small towns of comparable size. In addition, it was impossible to blind the interviewers to the exposure status of the two study groups. The possibility of safety considerations and non-blinding of interviewers as sources of selection and interviewer bias, respectively, are two methodological problems inherent in studying the effects of low intensity conflict and political violence.[27]

Our findings are consistent with other reports by medical investigators from the US[28–31] that the *contras* have deliberately killed, kidnapped, and injured civilian health workers and destroyed health facilities. The *contras* have reportedly killed more than 100 Nicaraguan health workers.[32] Through May 1986, the Nicaraguan Ministry of Health reports that 65 health facilities have been completely or partially destroyed by the *contras*, and an additional 37 health units have had to be closed due to the threat of *contra* attack.[15] The disruption of vaccination and malaria campaigns has been associated with measles outbreaks and a rising prevalence of reported malaria cases in the areas of the country most affected by the war.[33] Of 4,429 war-related deaths reported in Nicaragua on the Nicaraguan side of the conflict through May 1986, one-third were civilian non-combatant deaths, including 210 children under 12 years of age.[15]

This study provides further documentation of the destructive effects the war against Nicaragua is having on the lives of civilians in two rural communities, with these effects being most severe in the war zone. This raises several important concerns for health professionals and the US public. The data suggest that continued US support for the *contra* war may lead to continued suffering of the Nicaraguan civilian population, the ostensible beneficiaries of US foreign policy in Nicaragua. Reports of the deliberate targeting of health and education facilities are particularly disturbing, raising questions of the violation of the Geneva Convention protection of health workers during war.[34] Lastly, the pattern suggested by this and other reports should lead the US public to consider carefully the effects of "low intensity conflict" on the welfare of civilian populations before its further application in the Third World.

ACKNOWLEDGMENTS

We would like to give special thanks to John B. Wyon for his invaluable support, without which this project would not have been possible. We would

also like to thank David Bell, Richard Garfield, Larry Brown, Richard Cash, Hannah Hastings, Elise Levin, Terri Goldberg, Alejandro Mohar, Claudio Struchiner, and Mauricio Hernandez for their contribution. We are indebted to members of the Nicaraguan Ministries of Health and the people of Acoyapa and El Ostional for their cooperation in the study. We are also grateful to Thomas A. Louis, James M. Robins, John B. Willett, and Stephen W. Lagakos for helpful comments on the analysis.

This study was partially funded by grants from the John D. And Catherine T. MacArthur Foundation, the Samuel Rubin Foundation, and the Julian Mack Fund at the Harvard School of Public Health and sponsored by the Unitarian Universalist Service Committee.

Call for Papers:
Society for Health and Human Values Annual Meeting

The Society for Health and Human Values has announced a call for papers for its annual meeting, to be held October 26–29, 1989 in Washington, DC. Topics are sought in the humanities and health sciences, including, but not limited to, ethics, philosophy, religious studies, literature, history, creative arts, and law. Social science, educational evaluation, and health policy studies related to the humanistic aspects of health care are also welcomed.

Papers should have a maximum reading time of 20 minutes. Provide author identification on a separate cover sheet to ensure blind review. *Send papers* by June 15, 1989 to: SHHV Annual Meeting Program, 6728 Old McLean Village Drive, McLean, VA 22101. For *meeting information*, contact the program chair, John Moskop, PhD, Department of Medical Humanities, East Carolina University School of Medicine, Greenville, NC 27858-4354. Tel: (919) 551-2797.

A Methodology for Targeting Hospital Cases for Quality of Care Record Reviews

EDWARD L. HANNAN, PHD, HARVEY R. BERNARD, MD, JOSEPH F. O'DONNELL, MS, MA, AND HAROLD KILBURN, JR, MA

Abstract: We tested the efficacy of selected case characteristics in targeting quality of care problems for medical record review. The case characteristics, all of which apply to patients who die in a hospital, consist primarily of procedures and DRGs (diagnosis-related groups) for which death rarely occurs, and a set of complications of surgical care. All characteristics are obtainable from combinations of the principal and secondary diagnoses and procedures in the case, and are available from discharge abstracts.

The presence of a quality of care problem is confirmed through a review of the medical record by a nurse and two or more physicians.

A logistic regression model that controls for various patient and hospital variables is used as a measure of each of the proposed case characteristics. The results indicate that most of the characteristics are associated with higher percentages of quality of care problems than cases chosen at random, and that the methodology has promise as a tool for targeting cases for medical record review. (*Am J Public Health* 1989; 79:430–436.)

Introduction

In the last two decades, the costs of hospital care and other types of health care have risen more rapidly than the cost of living or the inflation rate. Partly as a result of the concentration of researchers and regulators on efforts to curtail these rising costs, hospital quality assurance initiatives have been relegated to a less important role than they deserve. Furthermore, it is feared that hospitals may have reduced diagnostic and therapeutic resources to patients, and discharged patients prematurely.[1]

Until recently, hospital quality assurance efforts have been quite limited. For the most part, surveys and quality of care reviews have relied on the first two of Donabedian's tripartite categorization of measures for judging quality: structure and process.[2] Quality of care researchers, regulators and review agencies have come to realize, however, that we must also incorporate Donabedian's third type of measure (outcome) into our reviews if we hope to accurately measure the quality of care in an institution.

A prime example of initiatives geared toward the use of outcome measures is the new agenda set forth by the Joint Commission on Accreditation of Healthcare Organizations, which is in the process of developing "clinical outcomes" to be reported by hospitals.

Several recent research studies have also used outcome measures to assess various aspects of quality of care in hospitals. A particularly well-researched issue has been the relation between the volume of patients treated at a hospital for a particular surgical procedure and the outcome achieved. Numerous studies reported that high surgical volumes for selected procedures are associated with better outcomes (lower mortality rates or shorter lengths of stay) for surgical patients.[3–6]

Another quality of care issue that has attracted considerable research attention is the "small area variations" in the rates of surgery for various procedures. Research by Wennberg and his associates[7–10] demonstrates that surgery rates among counties in the same state vary significantly even after adjusting for patient characteristics. This has led to the conclusion that physician practice patterns account for a significant percentage of observed differences.

Perhaps the most publicized efforts to develop outcome measures for quality of care in hospitals were the 1986 and 1987 reports by the Health Care Financing Administration (HCFA) that list hospitals with Medicare patient mortality rates significantly higher or lower than the national average.[11,*,†]

One shortcoming of the HCFA methodology involves the utility of the results for targeting purposes. Limited resources available to review organizations, state surveyors, accrediting agencies and hospitals as well as cost effectiveness concerns suggest a focus on reviews of selected *cases* (those most likely to evidence quality of care problems).

Another criticism of the HCFA model is that it has no proven link to the existence of quality of care problems. That is, it has not been proven that HCFA outlier hospitals have higher proportions of cases with quality of care problems (or deaths resulting from quality of care problems) than non-outlier hospitals. Recent studies by Dubois, *et al.*,[12,13] which use a methodology similar to HCFA's, are laudable in that a validation component is included. However, the database and the set of independent variables used in these studies are different from those used by HCFA.

The study described here is an attempt to identify hospital *cases* that are more likely to evidence quality of care problems than the average case. Our methodology is more suited than the HCFA methodology to integration with typical survey protocols, peer reviews, or hospital self-monitoring, all of which must identify specific hospital records to review.

The study has been confined to patients dying in a hospital. However, the number of in-hospital deaths generally exceeds the resources available for medical record reviews. Thus, the study attempts to define a subset of in-

hospital deaths for medical record review. It should be noted that the subset was not limited to deaths within 30 days of admission as in the HCFA study. The case characteristics that will be studied are referred to as targeting criteria. Although they apply primarily to surgical patients, some medical cases are included.

Methods

Identification of Targeting Criteria

The first step was to identify the case characteristics (targeting criteria) to be used in targeting a subset of in-hospital deaths in New York State in 1985 and 1986. To be effective as targeting criteria, these characteristics had to be retrievable from discharge data abstracts. Since 1980, every acute care hospital in New York State has been required to send a discharge data abstract to the State Department of Health for every inpatient stay. These abstracts contain information pertaining to demographics, dates of admission and discharge, diagnoses, procedures, admission status, and discharge disposition.

Given the available information and the decision to restrict the targeting to a subset of patients who died in the hospital, a set of 11 targeting criteria was proposed by a consultant surgeon. The intent was to select cases that would have a higher percentage of quality of care problems than cases without the criteria, as judged by medical record review. Appendix A describes each of the 11 criteria, which are not mutually exclusive.

There are two types of rare deaths; the only difference is that rare death diagnosis-related groups (DRGs) are used for the second criterion and rare death procedures are used for the first criterion. These rare death DRGs are similar to the "sentinel events" defined by Rutstein and his colleagues.[14]

Criteria (3) and (4), "death occurred within one day of surgery" and "death occurred two days after surgery," respectively, are based on the rationale that a patient dying shortly after surgery except for the exclusions noted may have experienced complications resulting from poor quality of surgical care or surgery that was inappropriate. The reason for using "within one day of surgery" and "exactly two days from surgery" was to evaluate any differences between the two. The intent was to combine these two criteria if both proved to be significant.

Criteria (5)–(9) include fluids/electrolyte imbalance, wound disruption or infection, acute renal failure, cardiopulmonary arrest, and other complications of surgery (mechanical complications of a device implant or graft, complications affecting specified body systems, and previously unspecified complications of surgical and medical care). For each of the criteria (5)–(9), the definition is such that the complication is coded as a secondary diagnosis in a surgical case with one or more non-diagnostic procedures. These cases are targeted because of the possibility that the complication occurred *during* the hospital stay.

Criteria (10) and (11), "burns from treatment" and "poisoning complications," are also specified as secondary diagnoses to increase the chance that they occurred during the hospital stay. They differ from criteria (5)–(9) in that they do not necessarily apply to surgical patients.

Case Sampling

To determine the effectiveness of the targeting criteria in identifying cases with quality of care problems, we identified retrospective samples of cases with and without the targeting criteria. We limited the sample selection to 104 hospitals reviewed by the Department's three downstate review agents. Resource constraints of the agents limited the total sample size to 8,109. Table 1 provides a breakdown of the sample by targeting criterion and review agent.

Since it was necessary to choose a sample with a sufficient number of cases having each of the targeting criteria, the sample was stratified so that it contained a higher percentage of cases with the targeting criteria than did the population of all in-hospital deaths. The resulting sample is not appropriate for estimating the percentage of quality of care problems that exist for cases with in-hospital deaths. For each case sampled, patient and facility characteristics (Appendix B) were also noted. These "control" variables were used in a multivariate model.

The first level of review of the medical record was performed by a registered nurse who determined whether the information appearing on the cover sheet (e.g., patient death, diagnoses, etc.) was correct. Any errors were noted and the correct information, determined after consultation with a medical record technician, was used to determine if the case should be reclassified as to the presence or absence of targeting criteria. Approximately 9 per cent of the cases

TABLE 1—Sample Sizes by Targeting Criterion and Review Agent

Targeting Criterion	IPRO**	CMR**	NYCHSRO†	Total	Percentage of Total Sample
Primary Surgical Procedures with Mortality Rate Less than 5%	330	141	135	607	7.5
DRGs with Mortality Rate Less than 5%	123	100	78	301	3.7
Death Occurred within 1 Day of any Surgical Procedure	675	378	317	1,371	16.9
Death Occurred on 2nd Day Following any Surgical Procedure	432	206	192	832	10.3

contained errors requiring correction. The record was next examined for any evidence of quality of care issues via a subjective review. If the nurse had any doubts regarding the quality of care rendered, the record was referred to a physician for review. Each physician was a board-certified specialist or sub-specialist who had experience performing quality of care review and utilization review. Quality of care was judged subjectively by the physician in two ways: first, whether the care departed significantly from professionally recognized standards; and second, if there was such a departure, whether it caused or contributed to the patient's death. In those instances where the physician identified a quality issue, the hospital was notified and given the opportunity to respond. Upon receipt of the hospital's response, one or more physicians reviewed all the case material and issued a final determination. For simplicity of exposition, this step will hereafter be referred to as the second physician review.

It should be noted that physicians and nurses were not apprised of either the targeting criteria or the cases that had one or more targeting criteria.

Reliability

Because of resource constraints, reliability could not be measured accurately. Cases in which the first physician found no quality of care problem were not reviewed by a second physician. Cases in which the first physician found a quality of care problem were reviewed by one or more additional physicians, but the second reviews were conducted with additional information supplied by the hospital. Nevertheless, 66 per cent of the time the second physician agreed with the first physician that a problem existed. This concordance would probably have been higher if both physicians had reviewed the same record prior to additional input by the hospital.

Data Analysis

From the sampling and record review just described, the following information was available for each case (record):

- the presence or absence of a quality of care problem;
- which, if any, of the targeting criteria were present;
- the status of each control variable (age, sex, race, payor, county, admission status, hospital size, hospital sponsorship, hospital teaching status, utilization review (UR) agent, year of death, length of stay.

This information was used to determine if, for each of the 11 targeting criteria, the percentage of quality of care problems was higher than the corresponding percentage for cases without the characteristics.

Since we wanted to compare the proposed targeting criteria with other alternatives (such as patient and facility characteristics) for targeting, we used a logistic regression model to predict the presence of quality of care problems (the dependent variable) as a function of the targeting criteria and the various patient and facility characteristics (the control variables). Because the sample of cases was stratified to include an overrepresentation of cases with targeting criteria, a single logistic regression model would have underestimated the relative strength of each targeting criterion (because it would be contrasted with a sample having an overly rich representation of other targeting criteria). Thus, 11 separate regression models were formulated. Each model consisted of all cases with a given targeting criterion, and a simulated random sample. The random sample was chosen by picking targeted and non-targeted cases in proportion to their presence in the general population of hospital cases. No cases with the specific targeting criterion being tested were in the random sample, however. Thus, each regression model tested the ability of a specific targeting criterion to identify quality of care problems in comparison with a random sample of cases, while controlling for the factors presented in the Appendix.

Results

Table 2 presents the results of the targeting process by targeting criterion. Column (1) presents the number of cases selected by criterion; column (2) presents the number reviewed by a nurse. Differences between the numbers in the two columns represent cases for which medical records were not available or (rarely) for which a patient death was erroneously coded. The third column presents, by criterion, the number and percentage of cases reviewed by the nurse that were forwarded to the first physician. The percentages of cases forwarded ranged from 6.5 per cent for the non-targeted cases to 35.9 per cent for "other complications of surgery." The average percentage of targeted cases that were forwarded was 15.5 per cent, indicating that the nurse was about 2.4 times more likely to forward a targeted case than a non-targeted case; also, the nurse did not know which cases were targeted.

Columns (4) and (5) present the number and percentage of cases in which care departed from standards and in which care caused or contributed to patient death, respectively. The percentage of cases in which care departed from standards was 3.9 per cent for all targeted cases and 1.7 per cent for non-targeted cases. For targeted cases, the percentages ranged from 9.8 per cent for rare death DRGs to 2.2 per cent for fluid/electrolyte imbalance.

For quality of care problems that caused or contributed to patient deaths, the percentage was 2.4 per cent for all targeted cases and 1.0 per cent for non-targeted cases. For targeted cases, the percentages of quality of care problems ranged from 5.7 per cent for rare death DRGs to .6 per cent for poisoning complications.

Logistic Regression Results

The results of the logistic regression model for the quality of care definition "care that departed from professionally recognized standards" are presented in Table 3 for the targeting criteria. The odds ratio given for each criterion is an estimate of the relative chance of a case with the criterion having a quality of care problem compared to cases without the criterion, while holding other variables constant.

As is indicated in Table 3, all but three of the targeting criteria (fluid/electrolyte imbalance, burns and poisonings) proved to have significantly higher rates of quality of care problems independent of the control variables. Although cases having two or more criteria had a higher percentage of quality of care problems, no interactions between criteria were significant in the regression model. They comprised only 10 per cent of the cases. Also, no interactions between targeting criteria and control variables were significant.

Hospitalizations in New York County (Manhattan), review by New York County Health Services Review Organization, hospitalizations in proprietary facilities, patients with lengths of stay less than four days, hospitalizations in non-teaching hospitals, and Black patients were all associated with higher rates of quality of care problems.

Table 3 also presents analogous results for care that caused or contributed to patient deaths. In addition to the three targeting criteria that were not significant for the other

*The total number of cases having each of the individual criteria is larger than the total because some cases have more than one criterion.

quality of care judgment, "wound disruption or infection" was also not significant. Thus, seven of the 11 criteria were significant for care that caused or contributed to patient deaths. Significant control variables were county (for four models), UR agent (two models), length of stay (one model), hospital sponsorship (four models), and primary payor (one model). For the variable "primary payor", Medicaid patients had higher rates of quality of care problems than patients of other payors.

Discussion

This study has demonstrated that information from uniform hospital discharge data sets can be used to target cases for quality of care review that have higher chances of having a quality of care problem than other cases. In contrast with methods for calculating adjusted hospital mortality rates for targeting, the approach presented here has been validated by medical record reviews. Furthermore, it is more useful in that it identifies specific cases in every hospital for review rather than just targeting a subset of hospitals. Also, certain

TABLE 3—Odds Ratios and Confidence Intervals for Targeting Criteria

Targeting Criterion	Care That Departed from Professionally Recognized Standards: Odds Ratio	Care That Departed from Professionally Recognized Standards: Confidence Interval for Odds Ratio	Care that Caused or Contributed to Patient Death: Odds Ratio	Care that Caused or Contributed to Patient Death: Confidence Interval for Odds Ratio

types of hospitals and patient characteristics are likely to be associated with quality of care problems.

Reweighting cases to simulate a random sample yields an overall percentage of 1.9 per cent for cases departing from standards and 1.2 per cent for cases in which care caused or contributed to patient deaths. Few studies in the literature provide a clue as to whether these percentages can be considered high or low. The study by Dubois, *et al.*[13] found more quality of care problems. Eighteen per cent of the deaths due to cerebrovascular accident, 24 per cent due to pneumonia, and 37 per cent of those due to myocardial infarction were judged to be "possibly preventable."

In a study conducted by the US Health and Human Services Department, 6.6 per cent of the 7,050 records reviewed were found to be receiving care that could be called poor quality—including improper diagnosis, treatment and therapy.[14] This percentage is about twice as high as that reported by the hospitals' federal peer review organizations.[15] The Medical Insurance Feasibility Study reviewed about 21,000 California hospital records and concluded that about 5 per cent of all admissions resulted in an injury caused by medical treatment.[16] A more recent study found that less than 1 per cent of hospital admissions are associated with poor care that results in temporary or permanent disability or death.[17] Thus, in general, the percentages reported in this study are lower than those reported in other studies. However, it is extremely difficult to compare results among studies because of the absence of uniformity in types of cases reviewed and in criteria for judging quality of care problems.

Despite the relative success of the study, several extensions would be beneficial. These include: enhancing the effectiveness of the targeting criteria, and developing other targeting criteria that will span the myriad of serious quality of care problems that occur in hospitals. Efforts to improve the effectiveness of the targeting criteria should focus on the incorporation of unambiguous severity of illness measures in definitions of the criteria. Severity of illness packages such as MedisGroups[18] and Computerized Severity Index[19] could be used to capture severity of illness at admission and then combined with the presence of post-admission complications to refine target definitions. The premise is that complications occurring during the hospital stay for patients with low severity of illness at admission will be more likely to be a result of poor hospital care.

With regard to the development of new criteria, two broad types of extensions can be explored. First, targeting can be expanded to include cases in which the patient did not die in the hospital. In some of these cases, the patient will have died a short time after discharge as a result of the complications. In other cases, the patient will not have died of the complications but will have experienced significant morbidity as a result of substandard hospital care.

The second means of expanding the current set of targeting criteria is to develop a set of medical complications to accompany the surgical complications. Some possibilities include infections; reactions from transfusions, injections and infusions; and vascular complications resulting from infusion, perfusion or transfusion. This extension is particularly important; in fact, many researchers feel that the majority of quality of care problems in hospitals are medical rather than surgical mishaps.

Another area that requires additional research is the development of protocols for quality of care determinations that are aimed at achieving maximum possible validity and reliability in decision making. As this was a pilot study, stringent validity and reliability tests were not included. However, given the relative success of the study, these issues will be addressed as part of a current effort of incorporating case targeting into New York State's new hospital surveillance program.

One particular concern is the validity of the judgments made by nurses in the initial screen. This is extremely important because most cases were not reviewed by physicians (they were screened out by nurses). In order to verify the validity of the nurse screens, a subset of cases screened out by nurses should be reviewed by physicians to ascertain that the physicians agree that no quality of care problems exist.

Unfortunately, limited resources did not allow for unbiased reliability tests in the study reported here. The best estimate, which was not a true estimate of reliability, was 66 per cent agreement on cases in which the first physician found a quality of care problem. However, we do not expect that any reliability problems would affect the *relative* percentages of quality of care problems for targeted and non-targeted cases, which was the focus of the study. Nevertheless, more work needs to be done in measuring the reliability of quality of care determinations and ensuring that it is at an acceptable level.

Our work should be interpreted in the light of related research. The study by Dubois, *et al.*,[13] is especially notable. As mentioned earlier, they used two types of quality of care review: a structured review that employed weighted process-of-care scales—11 for pneumonia and 10 each for cerebrovascular accident and myocardial infarction—and a review in which experts made subjective judgments as to whether the deaths were preventable. The former method found no differences in quality of care among high and low outlier hospitals whereas the latter method, which appears to be very similar to the subjective process used in this study, found that the high outliers had more preventable deaths than the low outliers. There is no way of determining whether either of the two results is valid. However, in assessing this anomaly, Dubois and colleagues imply that a major reason for the discrepancy may be that the structured approach was too myopic in only considering the specified criteria for noting a quality of care problem. With respect to reliability, however, the structured approach was superior.

The set of protocols and criteria developed by the Harvard Medical Practice Study Group in their ongoing study of medical injuries in New York State is also of value as a guide to improving validity and reliability.[‡] In this study, the Harvard Group defines an "adverse event" as a disabling injury inflicted upon a patient as a result of the process of medical management, whether it was negligent or not. Then, for adverse events, the probability of causation (how probable the condition was attributable to medical management rather than to the disease) and the probability of negligence (the probable contribution of negligence in medical management to the adverse event) are estimated.

APPENDIX A
Definition of Mortality Study Targeting Criteria

Criterion	Description
1) Primary Surgical Procedures with Mortality Rate Less Than 5%	Principal procedure associated with mortality less than 0.5 per cent in 1985 Exclusions: None
2) DRGs with Mortality Rate Less than 5%	DRGs associated with mortality less than 0.5 per cent in 1985 Exclusions: None
3) Death Occurred within 1 day of any Surgical Procedure	Death occurred on same date or day following surgical date Exclusions: • Patients with any diagnosis of selected neoplasms (196.0 to 198.89)* • Patients with unscheduled admission and admitting or primary diagnosis of injury or poisoning (800.00 to 995.89) • Selected surgical procedures • Diagnostic and therapeutic principal procedures (87.0 to 99.99)
4) Death Occurred on 2nd Day Following any Surgical Procedure	Death occurred on second day following surgical date Exclusions: Same as for Criterion 3
5) Surgical Case with Fluid Electrolyte Imbalance Reported as a Secondary Diagnosis	Surgical case with a secondary diagnosis of fluid electrolyte, or acid-base balance (276.0 to 276.9) Exclusions: Same as for Criterion 3, and • Admitting or primary diagnosis of fluid electrolyte, or acid-base balance (276.0 to 276.9)
6) Surgical Case with Infection or Wound Disruption Reported as a Secondary Diagnosis	Surgical case with a secondary diagnosis of wound disruption (998.3) Exclusions: • Diagnostic and therapeutic principal procedures (87.0 to 99.99)
7) Surgical Case with Renal Failure Reported as a Secondary Diagnosis	Surgical case with a secondary diagnosis of urinary complication (997.5) Exclusions: • Diagnostic and therapeutic principal procedures (87.0 to 99.99)
8) Surgical Case with Cardiopulmonary Arrest Reported as a Secondary Diagnosis	Surgical case with a secondary diagnosis of cardiac complication (997.1) Exclusions: • Diagnostic and therapeutic principal procedures (87.0 to 99.99)
9) Other Complications of Surgery	Surgical case with a secondary diagnosis of mechanical or other body system reaction (996.00 to 999.9) Exclusions: • Diagnostic and therapeutic principal procedures (87.0 to 99.99) • Patients with no secondary procedure • Cases with Criteria 7) and 8)
10) Burn is Reported as a Secondary Diagnosis	Burns as a secondary diagnosis (940.0 to 949.5) Exclusions: • Admitting or primary diagnosis of burn (940.0 to 949.5)
11) Poisoning is Reported as a Secondary Diagnosis	A secondary diagnosis of selected drug poisonings (960.0 to 989.0) Exclusions: • Admitting or primary diagnosis of selected drug poisonings (960.0 to 989.9)

APHA Releases Report on 'Illicit Drug Use and HIV Infection'

Illicit Drug Use and HIV Infection—The 3rd report of the Special Initiative on AIDS, a program activity of the American Public Health Association—has been released. This new report, prepared by the AIDS Working Group, summarizes the characteristics of illicit drug use and the scope and distribution of the HIV epidemic among intravenous (IV) drug users. Strategies to reduce the risk of HIV infection among drugs users are reviewed, including the need for education, health care, and drug treatment services upon demand, and strategies to promote safe sex.

To date, three reports have been issued in this AIDS Report Series. No. 1, *Casual Contact and the Risk of HIV Infection* was released July 1988; No. 2, *Contact Tracing and Partner Notification*, November 1988; and *Illicit Drug Use and HIV Infection*, January 1989. Single copies of the various reports are available for $3 each prepaid from APHA Publication Sales, 1015 15th Street, NW, Washington, DC 20005. Bulk rates available on request.

Coronary Arteriography and Coronary Bypass Survey among Whites and Other Racial Groups Relative to Hospital-based Incidence Rates for Coronary Artery Disease: Findings from NHDS

EARL FORD, MD, MPH, RICHARD COOPER, MD, ANGEL CASTANER, MD, BRIAN SIMMONS, MD, AND MAXINE MAR, RN, MPH

Abstract: To assess racial differences in health care utilization for coronary artery disease (CAD) the data of the National Hospital Discharge Survey (NHDS) from 1979-84 were examined. Discharge rates for acute myocardial infarction (AMI) were utilized as a measure of hospital-based incidence and relative need for the designated cardiac procedures. Although 35-74 year old Black men had discharge rates of AMI that were 77 per cent of those observed for White men, they underwent coronary arteriography half as often and were only a third as likely to have coronary artery bypass graft (CABG) surgery. Black women in this age range were hospitalized at a slightly higher rate than White women for AMI, yet experienced a 19 per cent lower rate of coronary arteriography and a 52 per cent lower rate of CABG surgery. These data suggest a racial bias in the pattern of care delivered for CAD in US hospitals at the present time. (*Am J Public Health* 1989; 79:437–440.)

Introduction

Despite a continuing controversy about the real rates of both incidence and mortality among Blacks from coronary artery disease (CAD), it remains by far the most common cause of death for both Blacks and Whites in the United States.[1,2] A higher rate of CAD at a younger age among Blacks, with a cross-over of age-specific rates around 70, is observed in the vital statistics data,[3] and this finding has recently been replicated in hospital-based incidence rates.[4] Several reports have also demonstrated shorter average survival among symptomatic Black patients with CAD compared to Whites,[5,6] especially among women.[6] Although coronary artery bypass graft (CABG) surgery probably has a minor effect—if any—on survival rates from CAD in the population, the quality of secondary prevention and post-MI care overall could be important.[7] Previous reports suggest that Blacks undergo fewer cardiac diagnostic procedures and subsequent surgery than do Whites.[8–10] We further examined the issue of racial differentials in the diagnosis and treatment of CAD in the random sample of US hospitals provided through the National Hospital Discharge Survey.

Methods

National Hospital Discharge Survey (NHDS) data tapes for the years 1979-84 were obtained from the National Center for Health Statistics (NCHS). The NHDS is an ongoing sample survey drawn from a frame of all short stay non-federal hospitals in the US. A description of the design and procedures of the NHDS has been published.[11]

Data from these tapes were analyzed for coronary arteriography (ICD9 CM codes 88.55 - 88.57), CABG surgery (ICD9 CM codes 36.10 – 36.19) and acute myocardial infarction (AMI) (ICD9 CM code 410). Race, which is not always found on discharge summaries, was missing from 8.6 to 13 per cent of records from 1979-84. Persons with race not stated were excluded from the present study. Procedures for identifying the race category "other" varied from year to year but consisted primarily of aggregating Blacks, native Americans, and Asians. For 1978, we determined that approximately 88 per cent of the recoded race category "other" was Black. Therefore, the use of the term Black must be regarded with caution, and it should be realized that some individuals of other races are included in this category.

Age, race, and sex specific population estimates of the numbers of AMI and cardiac procedures were obtained. We limited our analysis to the ages 35-74 years (grouped into 10 year age intervals) because outside this age range the numbers of records contained in the NHDS tapes for Blacks are often very small, and the number of procedures and AMI between the ages of 35 and 74 years constitute about 95 per cent of the total when all ages are considered. Population-based rates were calculated using the age, race (White and Black), and sex-specific estimated US civilian population data as the denominator. For the year 1980 the actual census data were used. Race-sex specific hospital discharge rates were age-adjusted to the 35-74 year old US population of 1980. Relative standard errors (RSEs) were derived from relative standard error curves published annually by the NCHS and documentation provided by the NCHS.* All standard errors are expressed as approximate relative standard errors (RSE). Separate examination of age-specific rates did not demonstrate a pattern that varied from the age-adjusted rates.

Hospitalization rates of AMI were utilized as an index of relative need for health care for CAD. In a previous analysis of NHDS data from 1972 through 1984 our group demonstrated that age-adjusted in-hospital case fatality rates from AMI were 19 per cent for Whites and 18 per cent for Blacks,[4] thus ensuring that the diagnosis, as reflected in the severity of outcome, was similarly applied in the two race groups. As estimates of health care utilization relative to need, ratios were generated between rates of arteriography, CABG surgery and AMI in the sex-race groups. Finally, the relation of principal source of payment and type of hospital to the number of discharges for AMI and procedures performed for

*Black:White

White and Black patients was examined using data collected by the NHDS.

The per cent of records with race not stated, the relatively small number of Blacks and other minorities sampled, and other methodological problems which arise with the use of the NHDS data for epidemiologic research[12] suggest caution in interpreting the data to be reported. Despite these reservations, the NHDS is the only data set allowing estimates of population rates of the procedures of interest, and the large proportion of Blacks in the "other" category permits at least tentative conclusions. Data analysis was performed on an IBM 3081K64 computer utilizing programs available on SAS.[13]

Results

Average rates for coronary arteriography, CABG surgery, and AMI are summarized for the six years in Table 1. Black men, when compared to White men, were only half as likely to undergo arteriography and a third as likely to have CABG surgery performed, despite an AMI rate of 77 per cent of that of White men. Less differential was observed in relative terms for women, with an arteriography rate of 81 per cent in Blacks compared to Whites, and CABG surgery rates one-half that of Whites.

In an effort to provide a summary index of health care utilization relative to need, we generated ratios of the rates of the two procedures to the rate of AMI for the four sex-race groups. For every 2.5 White men (RSE 3.2 per cent) and 2.5 White women (RSE 3.9 per cent) discharged with the diagnosis of AMI, one arteriogram was performed, while only one in 3.6 Black men (RSE 10.2 per cent) and one in 3.2 Black women with an AMI (RSE 7.2 per cent) had this procedure. For every 2.8 White men (RSE 3.3 per cent) discharged with AMI a CABG procedure was recorded, with the comparable figure of 6.2 (RSE 7.2 per cent) to one for Black men. Corresponding ratios of 9.9 (RSE 8.9 per cent) and 4.6 AMI per CABG surgery (RSE 4.4 per cent) were recorded for Black and White women, respectively. Thus, if the assumption is made that the ratio of AMI to arteriography and CABG surgery observed among Whites is the norm in the community, these secondary ratios provide an estimate of the degree to which Blacks are underserved. Despite varying rates of individual procedures/diagnoses, the estimate of health care utilization deficit is remarkably stable in the two sexes, yielding a 31 per cent (RSE 10.7 per cent) deficit among Black men and 22 per cent (RSE 8.2 per cent) deficit among Black women for arteriography relative to rates of AMI among Whites and a 50 per cent (RSE 7.9 per cent for men and 9.9 per cent for women) lower rate of CABG surgery for both sexes among Blacks relative to Whites.

The per cent distribution of White and Black patients by hospital type ownership is presented in Table 2. Although the data suggest some differences in the type of hospitals where care is delivered, the large standard errors preclude any definitive conclusions. However, Whites are less frequently hospitalized in proprietary hospitals for CABG surgery. Concerning sources of payment, reimbursement for AMI for Blacks was more likely to originate from various government programs whereas reimbursement for coronary arteriography was more likely to originate from Medicaid in addition to various government programs (Table 3).

*Unstable estimate
†Includes workers' compensation, Title V, and other government programs
‡Includes self-pay, no charge, and other sources of payment

Discussion

The results reported here suggest that, between 1979 and 1984, the Black population in the US received substantially less tertiary health care for CAD as measured by coronary arteriography and CABG surgery than Whites relative to a hospital-based measure of AMI incidence. It should be clear that these data do not reflect true incidence rates of CAD in the community; in fact, higher out-of-hospital sudden CAD rates have been reported among Blacks, and there is at least some evidence that CAD is diagnosed late at the catheterization laboratory in some centers.[1,2,14] True population rates of CAD, therefore, are likely to be even higher among Blacks, particularly women. This study examined only the response of US hospitals to patients that were discharged with one form of CAD, namely AMI. As noted previously the in-hospital case fatality rates from Blacks with AMI was identical to that of Whites,[4] suggesting at least that there was no bias toward milder cases. Data from at least one study indicate that the rate of normal coronary arteries found at catheterization is much higher in Blacks than Whites, and this would reduce the need for subsequent CABG surgery in that group.[15] In the context of the NHDS data for AMI it seems most likely, however, for the US as a whole this reflects the fact that appropriate patients are not receiving catheterization, rather than a true low rate of CAD.

Tertiary care for CAD is expensive and this fact helps to explain the race differences in health care utilization observed in this study. This study presents evidence that various government programs shoulder a greater burden for payment for hospitalizations for AMI and cardiac procedures among Blacks. In an entirely separate national probability sample, Young noted that the rate of CABG surgery in privately insured or self-paying patients was 9 per cent or higher, and only 2 per cent for those on public aid.[10] Multivariate analysis confirmed the importance of economic factors, and showed higher rates among Whites; higher CABG surgery rates were likewise observed in more affluent areas with more physicians and hospital beds relative to the population.[10] At a single university hospital it was observed that the rate of CABG surgery following arteriography was much lower among Blacks than Whites, and this could not be explained by clinical characteristics of the patients.[8] Maynard, *et al.* reported the same pattern from the data of the Coronary Artery Surgery Study.[9] Evidence suggests that the level of care for cardiovascular disease for Blacks is lower than for Whites in other measures of health care utilization.[16,17]

The present analysis suggests that these differentials reflect a biased institutional response since the burden of CAD reported in the same survey does not justify lower rates of cardiac procedures in Blacks. In view of increasing pressure for cost containment, and the growing reluctance of private hospitals to serve patients without adequate financial resources, it seems unlikely that these differentials will disappear in the foreseeable future. Recent evidence that the decline in CAD over the past 10 years among Blacks is slower than that of White men[18] further suggests that the unmet need for CABG surgery will remain greater among Blacks than among Whites.
